An unborn baby is at greatest risk for serious problems when the mother becomes infected with CMV for the first time while pregnant. About 10% of these babies will be born with obvious problems, including **prematurity**, lung problems, an enlarged liver and spleen, **jaundice**, anemia, low birth weight, small head size, and inflammation of the retina. About 90% of these babies may appear normal at birth. About 20% will later develop severe hearing impairments and intellectual disabilities (ID). Pregnant women 25 years and older who are immune to CMV are much less likely to pass the virus to their babies than younger women who have never been exposed to CMV.

Diagnosis

Tests

CMV can be detected using fluid or tissue cultures, blood testing, antigen assays, qualitative polymerase chain reaction (PCR) testing of blood and tissue samples, and by cytopathology.

Body fluids or tissues can be tested to reveal CMV infection. However, this information is not always particularly helpful because CMV stays dormant in the cells for life. Tests to look for special immune cells (antibodies) directed specifically against CMV are useful in proving that a person has been infected with CMV. These tests do not give any information regarding when the CMV infection first occurred.

A newer test, the anti-CMV immediate early antigen monoclonal antibody test, can detect CMV infection as early as three hours after infection with CMV.

Treatment

Drugs

Ganciclovir (Cytovene) and valganciclovir (Valcyte) are antiviral medications that have been used to prevent CMV in high-risk patients (such as solid organ

KEY TERMS

Cervix—The narrowed, lowest part of the uterus through which a baby must pass in order to enter the birth canal.

Congenital—A condition that exists before birth and at birth.

Placenta—The organ that provides oxygen and nutrition from the mother to the unborn baby during pregnancy. The placenta is attached to the wall of the uterus and leads to the unborn baby via the umbilical cord.

transplant patients) or to treat patients infected with CMV. Treatment with intravenous ganciclovir is the preferred treatment for CMV. Valganciclovir, which is given orally once per day, may be used to treat some cases of existing CMV and has proved to be very effective when used for CMV **prophylaxis** in high-risk patients. It should not be used in patients with pre-existing **kidney disease**. Another antiviral medication, foscarnet (Foscavir), may be used to treat patients whose CMV infection has not responded to treatment with ganciclovir.

Antiviral drugs are not used to treat CMV infection in otherwise healthy patients because the drugs have significant side effects that outweigh their benefits.

Prognosis

Prognosis in healthy people with CMV infection is excellent.

About 0.1% of all newborn babies will have serious damage from CMV infection occurring while they were developing in the uterus.

Despite lengthy treatment courses with valganciclovir, relapse of CMV disease remains common among organ transplant recipients.

Prevention

Prevention of CMV infection in the normal, healthy person involves good handwashing. Blood products can be screened or treated to insure that they do not contain CMV.

Individuals who engage in high-risk behaviors, such as engaging in sexual activities with multiple sexual partners, should be educated as to their risk for infection with CMV.

Dacryocystitis

Definition

Dacryocystitis is an inflammation of the tear sac (lacrimal sac) at the inner corner of the eye.

Description

Tears drain into little openings (puncta) in the inner corners of the eyelids. From there, the tears travel through little tube-like structures (canaliculi) to the lacrimal sac. The nasolacrimal ducts then take the tears from the lacrimal sac to the nose. That's why people need to blow their nose when they cry a lot.

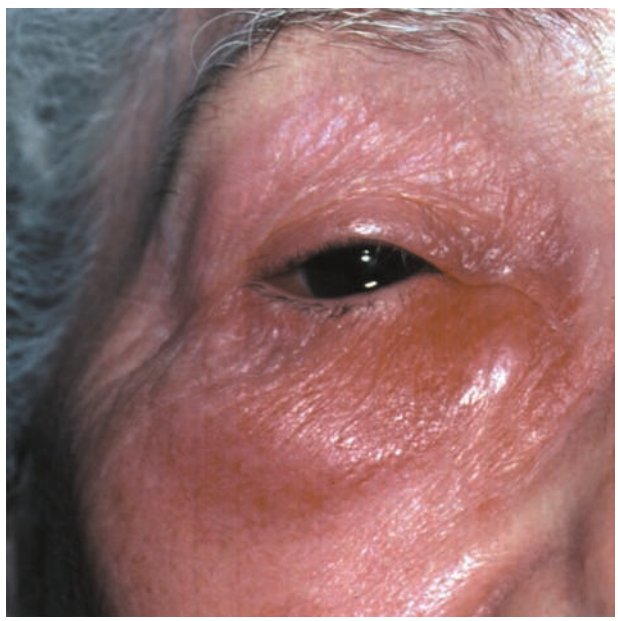
Dacryocystitis is usually caused by a blockage of the nasolacrimal duct, which allows fluid to drain into the nasal passages. When the lacrimal sac does not drain, bacteria can grow in the trapped fluid. This condition is most common in infants and people over 40 years old.

Causes and symptoms

In newborn infants, the nasolacrimal duct may fail to form an opening—a condition called dacryostenosis. The cause of dacryocystitis in adults is usually associated with inflammation and infection in the nasal region. Dacryocystitis can be acute, having a sudden onset, or it can be chronic, with symptoms occurring over the course of weeks or months. Symptoms of acute dacryocystitis can include **pain**, redness, tearing, and swelling at the inner corner of the eye by the nose. In chronic dacryocystitis, the eye area may be swollen, watery or teary, and, when pressure is applied to the area, there may be a discharge of pus or mucus through the punctum.

Diagnosis

Dacryocystitis usually occurs in only one eye. As mentioned, the symptoms can range from watery eyes, pain, swelling, and redness to a discharge of pus when pressure is applied to the area between the bridge of the nose and the inner eyelids. A sample of the pus may be collected on a swab or in a tube for laboratory analysis. The type of antibiotic and treatment may depend on which bacteria is present. In the acute form, a blood test may reveal an elevated white blood cell (WBC) count; with a chronic infection, the WBC count is usually normal. To identify the exact location of the blockage, an x ray can be taken after a dye is injected into the duct in a procedure called dacryocystography.



Dacryocystitis of the right eye. The inner corner of the lower lid is bulging from an inflamed tear sac. Blockage of the tear duct causes fluid to be trapped in the tear sac, which becomes infected. *(Custom Medical Stock Photo, Inc.)*

KEY TERMS

Canaliculi—Also known as lacrimal ducts, these tube-like structures carry the tears from the eyes to the lacrimal sac.

Cannula—A narrow tube that can be inserted into a duct.

Dacryocystography—An x ray of the tear duct after injection of a dye that is used to help locate a blockage in the duct.

Dacryocystorhinostomy—A surgical procedure to drain the tear sac into the nasal passage.

Dacryostenosis—Obstruction or narrowing of the nasolacrimal duct. May be present at birth.

Nasolacrimal duct—The tube that carries the tears from the lacrimal sac to the nose.

Punctum—Tiny opening at the inner corners of the upper and lower lids. The area for the beginning of tear drainage.

Treatment

A warm compress applied to the area can help relieve pain and promote drainage. Topical and oral **antibiotics** may be prescribed if an infection is present. Intravenous antibiotics may be needed if the infection is severe. In some cases, a tiny tube (cannula) is inserted into the tear duct which is then flushed with a sterile salt water solution (sterile saline). If other treatments fail to clear up the symptoms, surgery (dacryocystorhinostomy) to drain the lacrimal sac into the nasal cavity can be performed. In extreme cases, the lacrimal sac will be removed completely.

In infants, gentle massage of the lacrimal sac four times daily for up to nine months can drain the sac and sometimes clear a blockage. As the infant grows, the duct may open by itself. If the duct does not open, it may need to be dilated with a minor surgical procedure.

Prognosis

Treatment of dacryocystitis with antibiotics is usually successful in clearing the infection that is present. If there is a permanent blockage that prevents drainage, infection may recur and surgery may be required to open the duct. If left untreated, the infected sac can rupture, forming an open, draining sore.

Prevention

There are no specific recommendations for the prevention of dacryocystitis, however, good hygiene may decrease the chances of infection.

DASH diet

Definition

DASH stands for Dietary Approaches to Stop **Hypertension**. The DASH diet is a dietary pattern based on the findings of studies that show beneficial effects on hypertension and blood lipids, the first of which was based on results published in 1997, along with the 2010 **Dietary Guidelines** for Americans, which recommend reducing the amount of **sodium**, or salt, in daily **diets** to lower risk of cardiovascular disease.

Description

The DASH diet is based on 2,000 calories a day with the following nutritional profile:

- Total fat: 27% of calories
- Saturated fat: 6% of calories
- Protein: 18% of calories
- Carbohydrate: 55% of calories
- Cholesterol: 150 mg
- Sodium: 2,300 mg
- Potassium: 4,700 mg
- Calcium: 1,250 mg
- Magnesium: 500 mg
- Fiber: 30 g

These percentages translate into more practical guidelines using food group servings.

- Grains and grain products: Seven to eight servings per day. One serving is equivalent to one slice of bread, half a cup of dry cereal, or cooked rice or pasta. These foods provide energy, carbohydrates, and fiber.

WWW.BOOKBAZ.IR

- Vegetables: Four to five servings per day. One serving size is one cup leafy vegetables, half-cup cooked vegetables, or half-cup vegetable juice. Fruits and vegetables provide potassium, magnesium, and fiber. Consuming the full number of vegetable servings is a key component of the diet.
- Fruits: Four to five servings per day. One serving is one medium fruit, half-cup fruit juice, or one-quarter cup dried fruit.
- Low-fat dairy foods: Two to three servings per day. One serving is equivalent to one cup milk or yogurt or 1 oz (30 g) cheese. Dairy provides rich sources of protein and calcium.
- Meat, fish, poultry: Two or fewer servings per day. One serving is 2.5 oz (75 g). The emphasis is on lean meats and skinless poultry. These provide protein and magnesium.
- Nuts, seeds, and beans: Four to five servings per week. Portion sizes are half a cup of cooked beans and two tablespoons of seeds. These are good vegetable sources of protein, as well as magnesium and potassium.
- Fats and oils: Two to three servings per day. One serving is one teaspoon (tsp.) of oil or soft margarine. Fat choices should be heart healthy unsaturated sources (canola, corn, olive, or sunflower). Saturated and *trans* fat consumption should be decreased.
- Sweets: Five servings per week. A serving is one tablespoon of pure fruit jam, syrup, honey, and sugar. The plan still allows for treats, but the healthier the better.

An example breakfast menu is: cornflakes (one cup) with 1 tsp. sugar, skim milk (one cup), orange juice (1/2 cup), a banana, and a slice of whole wheat bread with one tablespoon jam. Suggested snacks during the day include dried apricots (1/4 cup), low-fat yogurt (one cup), and mixed nuts (1.5 oz or 40 g).

These guidelines are available in the National Institutes of Health (NIH) updated booklet, "Your Guide to Lowering Your Blood Pressure with DASH," which also provides background information, weekly menus, and recipes.

Although the DASH diet provides two to three times the amount of some nutrients currently consumed in the average American diet, the recommendations are not dissimilar to the 2010 U.S. dietary guidelines, published by the U.S. Department of Agriculture (USDA) and U.S. Department of Health and Human Services. The main difference is the emphasis on more fruit and vegetable servings. In addition, it separates nuts, seeds, and beans from the meat, fish, and poultry food groups and recommends four to five weekly servings of nuts, seeds, and dry beans.

The DASH diet was not designed for weight loss, but it can be adapted for lower calorie intakes. The NIH booklet provides guidelines for a 1,600-calorie diet. Vegetarians can also use the diet, as it is high in fruits, vegetables, beans, seeds, and low-fat dairy, which are the main sources of protein in a vegetarian diet.

Origins

High blood pressure affects about one in three adults in the United States. Globally, hypertension is responsible for more than 9 million deaths each year. High blood pressure is defined as blood pressure consistently above 140/90 mmHg. The top number, 140, is the systolic pressure exerted by the blood against the arteries, while the heart is contracting. The bottom number, 90, is the diastolic pressure in the arteries while the heart is relaxing or between beats. The concern is the higher the blood pressure, the greater the risk for developing **heart disease**, **kidney disease**, and **stroke**. High blood pressure is known as the silent killer as it often has no symptoms or warning signs.

The 1997 DASH study results showed that a diet rich in fruits, vegetables, and low-fat dairy foods, with reduced saturated and total fat, could substantially lower blood pressure. The DASH diet, which also emphasizes low use of salt in foods, is recommended by the National Heart, Lung and Blood Institute (NHLBI; part of the National Institutes of Health) for lowering blood pressure and reducing risk of cardiovascular disease.

The DASH study by the NHLBI, published in the *New England Journal of Medicine* in 1997, was the first study to look at the effect a diet rich in potassium, magnesium, and **calcium**, not supplements, had on blood pressure.

The study involved 459 adults with and without high blood pressure. Systolic blood pressures had to be less than 160 mmHg and diastolic pressures 80 to 95 mmHg. Approximately half the participants were women and 60% were African American. Three eating plans were compared. The first was similar to a typical American diet—high in fat (37% of calories) and low in fruit and vegetables. The second was the American diet but with more fruits and vegetables. The third was a plan rich in fruits, vegetables, low-fat dairy foods, and low in overall fat (less than 30% of calories). It also provided 4,700 mg potassium, 500 mg magnesium, and

1,240 mg calcium per 2,000 calories. This has become known as the DASH diet. All three plans contained equal amounts of sodium, about 3,000 mg of sodium daily, equivalent to 7 g of salt. This was approximately 20% below the average intake for adults in the United States and close to the current salt recommendations of 4–5 g. Calorie intake was adjusted to maintain each person's weight. These two factors were included to eliminate salt reduction and weight loss as potential reasons for any changes in blood pressure. All meals were prepared for the participants in a central kitchen to increase compliance with the diets.

Results showed that the increased fruit and vegetable and DASH plans lowered blood pressure, but the DASH plan was the most effective. For participants without high blood pressure, it reduced systolic pressure by 6 mmHg and diastolic by 3 mmHg. The results were better for participants with high blood pressure: The drop in systolic and diastolic was almost double, at 11 mmHg and 6 mmHg, respectively. These results showed that the DASH diet appeared to lower blood pressure as well as a 3 g salt-restricted diet but, more importantly, had a similar reduction as seen with the use of a single blood pressure medication. The effect was seen within two weeks of starting the DASH plan, which is also comparable to treatment by medication, and continued throughout the trial. This trial provided the first experimental evidence that potassium, calcium, and magnesium are important dietary factors in affecting blood pressure, rather than just sodium alone.

The original DASH plan did not restrict sodium. As a result, a second DASH-sodium trial from 1997–1999 (published in 2001) studied the effect the DASH diet had on blood pressure using different sodium levels (3,300, 2,300 or 1,500 mg). This is known as the DASH-sodium diet. The highest amount of salt recommended by the U.S. Department of Agriculture's (USDA) 2010 *Dietary Guidelines for Americans* is 2,300 mg. The amount recommended by the Institute of Medicine, as a minimum to replace the amount lost through urine and to achieve a diet that provides sufficient amounts of essential nutrients, is 1,500 mg. The results showed that the combined effect of a lower sodium intake with the DASH diet was greater than just the DASH diet or a low salt diet. Like earlier studies, the greatest effect was with the lower sodium intake of 1,500 mg, particularly for those without hypertension. For this group, the systolic blood pressure dropped about 7 mmHg and the diastolic about 4 mmHg. However, the reduction in blood pressure for people with hypertension was about 12 mmHg for systolic and 6 mmHg for diastolic, quite similar to the reductions seen with the DASH diet.

Function

The DASH meal plan is a healthy diet recommended for those with and without high blood pressure.

Benefits

The DASH diet may lower blood pressure as much as taking medication, but without the risk of unwanted side effects. The dietary changes can also have immediate effects comparable with drug therapy. A blood pressure reduction of the degree seen in the DASH study is estimated to reduce the incidence of **coronary artery disease** by 15% and stroke by 27%.

The DASH plan may also lower blood pressure just as well as restrictive low-salt diets of 3–4 g of salt per day. Many people find low-salt foods to be bland, and with 70–80% of salt intake coming from processed foods, including baked foods such as breads, people may have trouble adhering to low-salt diets. The DASH diet is an adaptation to healthy eating, so it has no restrictions but instead follows standard dietary guidelines for the general public. In addition, some studies suggest that the DASH diet is associated with slowing of cognitive decline in the elderly and better insulin sensitivity in people who are diabetic.

Precautions

Adding high-fiber foods to the diet should be done gradually to avoid side effects such as gas, bloating, and **diarrhea**. It is important to increase fluid at the same time, as fiber draws water into the bowel. High fiber intake with inadequate fluid can cause hard stools and **constipation**. Being active is helpful in reducing negative symptoms.

Increasing fruits and vegetables increases the potassium content of the diet. For healthy people with normal kidney function, a higher potassium intake from foods does not pose a risk as excess potassium is excreted in the urine. However, individuals whose urinary potassium excretion is impaired, such as those with end-stage renal disease, severe **heart failure**, or adrenal insufficiency, may be at risk of **hyperkalemia** (high levels of potassium in the blood). Hyperkalemia may cause cardiac **arrhythmias** (irregular heartbeat), which could be serious. Some common drugs can also decrease potassium excretion. Individuals at risk should consult a doctor before starting the DASH diet, as higher potassium intakes in the form of fruit and vegetables may not be suitable.

WWW.BOOKBAZ.IR

Care should also be taken with potassium containing salt substitutes.

Risks

As of 2014, there were no known risks associated with the DASH diet. Long-term effects of the diet on morbidity and mortality were unknown.

Research and general acceptance

Some studies have suggested high intakes of salt play a role in the development of high blood pressure. However, the use of low-salt diets for the prevention or treatment of high blood pressure has come into question from time to time. The Trials of Hypertension Prevention Phase II in 1997 indicated that energy intake and weight loss were more important than the restriction of dietary salt in the prevention of hypertension. A 2006 Cochrane review, which looked at the effect of longer-term modest salt reduction on blood pressure, found that modest reductions in salt intake could have a significant effect on blood pressure in those with high blood pressure, but a lesser effect on those without. It was agreed that the 2007 **public health** recommendations of reducing salt intake from levels of 9–12 g/day to a moderate 5–6 g/day would have a beneficial effect on blood pressure and cardiovascular disease.

The effectiveness of the DASH diet for lowering blood pressure is well recognized. The 2010 Dietary Guidelines for Americans recommends the DASH Eating Plan as an example of a balanced eating plan consistent with the existing guidelines and it forms the basis for the USDA MyPlate. DASH is recommended in other guidelines such as those advocated by the British Nutrition Foundation, American Heart Association, and American Society for Hypertension. *U.S. News and World Report* ranked the DASH diet as the "Best Overall Diet" for four years in a row.

Although reducing sodium and increasing potassium, calcium, and magnesium intake play key roles in lowering blood pressure, the reasons why the DASH eating plan has a beneficial effect remain unclear. Researchers suggest it may be because whole foods improve how the body absorbs potassium, calcium, and magnesium, or it may be related to the effect of eating these nutrients together instead of eating them individually.

Some debate also continues as to whether reducing salt is beneficial for control of heart disease or for general health. In August 2014, a worldwide study reported that eating too little salt is also harmful. The American Heart Association questioned the findings, continuing to encourage limitations in salt for heart health. One of the study authors expressed the need to use salt in moderation. This is especially true for some people with diseases such as heart failure, who need to balance sodium, potassium, and other substances in their body.

Governments and health associations have urged the food industry to reduce the salt in processed foods. Most salt in the diet comes from prepared foods, not from salt shakers. The New York City Health Department spearheaded the National Salt Reduction Initiative in the United States, and a number of other health-related organizations joined this effort. The coalition worked closely with food manufacturers and restaurants that voluntarily agreed to reduce sodium levels in their products. Some already met 2014 targets for sodium reduction, and the initiative was measuring sodium intake of people in New York to test the health effects. In addition, the U.S. Department of Health and Human Services, along with several other federal and private sector organizations, led the Million Hearts initiative. The goal was to prevent the occurrence of one million heart attacks and strokes in the United States by 2017. Reduction of sodium levels in the diet to aid in lowering blood pressure was a major component of this initiative as well.

Whether patients can follow the DASH diet long-term has been debated. The 2003 PREMIER Clinical Trial (a multi-center trial) studied the effects of diet on blood pressure and found that the DASH diet results were less than the original study. This difference was thought to be because participants in the DASH study were supplied with prepared meals, whereas participants in the PREMIER study prepared their own foods. As a result, only half the fruit and vegetable intake was achieved in the PREMIER study, which affected the overall intakes of potassium and magnesium. The researchers concluded that compliance with the DASH diet in the long term is questionable but agreed that patients should still be encouraged to adopt healthy interventions such as the DASH diet, as it does offer health benefits.

In terms of heart health, the DASH diet lowered total **cholesterol** and LDL cholesterol, but it was also associated with a decrease in high-density lipoprotein (HDL), the so-called good cholesterol. Low HDL levels are considered to be a risk factor for coronary heart disease, whereas high levels are thought to reduce the likelihood of heart disease. The decrease was greatest in individuals who started with a higher level of the protective HDL. Researchers agree that the reasons for the decrease in HDL levels need further review, but they concluded that the overall effects of

KEY TERMS

Diastolic blood pressure—The point at which arterial pressure is lowest (when the ventricles are relaxed). The second measurement (usually the lower number) in a blood pressure reading.

Hypertension—Another term for high blood pressure.

Mediterranean diet—A diet based on the eating habits of people living in the Mediterranean region. It emphasizes fruits, vegetables, nuts, grilled seafood and poultry, olive oil, and a glass of red wine daily. There is little to no red meat, butter, or eggs.

Systolic blood pressure—The point at which arterial pressure is highest (when the ventricles are contracting). The first measurement in a blood pressure reading.

the DASH diet are beneficial in terms of preventing heart disease.

Although the long-term health effects of the DASH diet were not established as of 2014, the diet closely resembles the **Mediterranean diet**, which has been shown to have other health benefits, including a reduced risk for heart disease and cancer rates. It is thought that the DASH diet is likely to offer similar health benefits.

Death and dying

Definition

Death is the end of life, a permanent cessation of all vital functions. Dying refers to the body's preparation for death. This process may be very short in the case of accidental death, or it can last weeks or months, such as in patients suffering from cancer.

Description

Death may come when surgery is performed. All surgeries carry some risk, but the type and severity of surgical risk is dependent upon many factors, including the type of surgery, the general health of the patient, and the type of **anesthesia**. Patients should discuss potential risks with their surgeon and anesthesiologist prior to the procedure. Specific standards are set by the American Society of Anesthesiologists to

WWW.BOOKBAZ.IR

enhance the safety and quality of anesthesia before surgery, basic methods of monitoring patients during surgery, and patient care during recovery.

Some risk factors related to death during surgery include increasing age, emergency surgery, and general postoperative complications including cardiac, renal, or pulmonary complications. Age-related changes in the immune system play a significant role in the increased risk of infection, decreased ability to fight diseases, and slower wound healing after surgery. An **aging** body is more susceptible to subsequent infections because of previous illness or surgery and the subsequent weakening of the immune system. Anti-inflammatory medications (e.g., to control conditions such as arthritis), which many older people may take, are also known to slow wound healing. Some studies have investigated whether the volume of surgeries performed within an institution affects surgical results, and volume may be an important consideration when choosing a hospital.

Complications of surgery

According to Ohio State University's Wexner Medical Center, some of the most common complications related to surgery include **shock**, hemorrhage, infection, **blood clots**, pulmonary complications, urinary retention, and adverse reactions to anesthesia. Additional side effects include nausea or **vomiting**, soreness, loss of sleep, and **constipation**.

A study published in the journal *JAMA Surgery* (*Journal of the American Medical Association*, formerly the *Archives of Surgery*) found that the following procedures had the highest rates of complications:

- enteric fistula repair
- pancreatic surgery
- proctectomy
- small bowel surgery
- esophagectomy

Preparing for death or incapacitation

An advance directive is a document that lets caregivers know a patient's wishes, should the patient become unable to make medical decisions. The hospital must be told about a patient's advance directive at the time of admission. Descriptions of the type of care desired for different levels of illness should be included in the document. For instance, a patient may wish to have or not to have a certain type of care in the case of terminal or critical illness or unconsciousness. The advance directive protects the patient's wishes in these situations.

A living will is a type of advance directive that may take effect when a patient has been deemed terminally ill. Terminal illness assumes a life span of six months or less. A living will allows the patient to outline treatment options without interference from an outside party.

A durable power of attorney for health care (DPA) is similar to a living will; however, it goes into effect any time the patient becomes unconsciousness or unable to make informed medical decisions. The DPA designates a family member or friend to make medical decisions on behalf of the patient.

While both living wills and DPAs are legal in most states, there are some states that do not officially recognize these documents. However, they may still be used to guide families and doctors in treatment wishes.

Do-not-resuscitate (DNR) orders can be instituted by including them in an advance directive or by informing hospital staff. Unless instructions for a DNR are in effect, hospital staff will make every effort to revive patients whose hearts have stopped or who have stopped breathing. DNR orders are recognized in all states and will be incorporated into a patient's medical chart if requested. It is recommended that patients interested in a DNR discuss this option with his or her physician before loss of mental faculties.

Any of these documents can be completed by an attorney or authorized by a notary. A copy should be given to the doctor and to a trusted family member.

Mourning and grieving

The death of a loved one is a severe **trauma**, and the grief that follows is a natural and important part of life. No two people grieve exactly the same way, and cultural differences play a significant part in the grieving process. For many, the immediate response may be shock, numbness, or disbelief. Physical reactions may include **shortness of breath**, heart **palpitations**, sweating, and **dizziness**. Other reactions might be a loss of energy, sleeplessness or increase in sleep, changes in appetite, or stomach aches. Susceptibility to common illnesses, nightmares, and dreams about the deceased are not unusual during the grieving period.

Emotional reactions are as individual as physical reactions. A preoccupation with the image of the deceased or feelings of hostility, apathy, emptiness, or even fear of one's own death may occur. Depression, diminished sex drive, sadness, and anger at the deceased may be present. **Bereavement** may cause short- or long-term changes in the family unit or other relationships of the bereaved.

It is important for the bereaved to work through their feelings and to not avoid their emotions. Support groups are often available. If a person does not feel comfortable discussing emotions and feelings with family members, friends, or primary support groups, they may wish to consult a therapist to assist with the process.

Various cultures and religions view death in different manners and may conduct mourning rituals according to their own traditions. Visitors often come to express their condolences to the family and to bid farewell to the deceased. Funeral services may be public or private. Family or friends of the deceased may host a gathering after the funeral to remember and celebrate the life of the deceased, which also helps the bereaved to begin the mourning process positively. Knowing how much a loved one is cherished and remembered by friends and family can provide comfort to those who experienced the loss. Other methods of condolences include sending flowers or cards to the home or the funeral parlor, sending a donation to a charity that the family has chosen, or bringing a meal to the family during the weeks after the death.

Preparation

Although it is not always possible, death preparation can sometimes help to reduce **stress** for the dying person and their family. Some preparations that can be done beforehand include:

- Inform one or more family members or the executor of the estate about the location of important documents, such as social security card, birth certificate, and others.
- Take care of burial and funeral arrangements (such as cremation or burial, small reception or full funeral) in advance of death, or inform family members or a lawyer what these arrangements should be.
- Discuss financial matters (such as bank accounts, credit card accounts, and federal and state tax returns) with a trusted family member, lawyer, estate executor, or trustee.
- Gather together all necessary legal papers relating to property, vehicles, investments, and other matters relating to collected assets.
- Locate the telephone numbers and addresses of family and friends that should be contacted upon the death.
- Discuss outstanding bills (such as utilities, telephone, and house mortgage) and other expenses that need to be paid.
- Collect all health records and insurance policies.
- Identify the desire to be an organ donor, if any.

KEY TERMS

Anesthesia—Loss of sensation and usually of consciousness without loss of vital functions, artificially produced by the administration of one or more agents that block the passage of pain impulses along nerve pathways to the brain.

Anesthesiologist—A physician specializing in administering anesthesia.

Electrocautery—The use of a low-voltage electrified probe used to remove tissue through cauterization (burning).

Endoscopic—Of, relating to, or performed by means of an endoscope or endoscopy.

Euthanasia—To bring about the death of another person who has an incurable disease or condition.

Nosocomial—Originating or taking place in a hospital.

Percutaneous—Performed through the skin.

Debridement

Definition

Debridement is the process of removing dead (necrotic) tissue or foreign material from and around a wound to expose healthy tissue.

Purpose

An open wound or ulcer can not be properly evaluated until the dead tissue or foreign matter is removed. **Wounds** that contain necrotic and ischemic (low oxygen content) tissue take longer to close and heal. This is because necrotic tissue provides an ideal growth medium for the bacteria that causes gas **gangrene**, such as *Clostridium perfringens*. Though a wound may not necessarily be infected, the bacteria can cause inflammation and strain the body's ability to fight infection. Debridement is also used to treat pockets of pus called abscesses. Abscesses can develop into a general infection that may invade the bloodstream (**sepsis**) and lead to **amputation** and even death. Burned tissue or tissue exposed to corrosive substances tends to form a hard black crust, called an eschar, while deeper tissue remains moist and white, yellow and soft, or flimsy and inflamed. Eschars may also require debridement to promote healing.

Description

The four major debridement techniques are surgical, mechanical, chemical, and autolytic.

Surgical debridement

Surgical debridement (also known as sharp debridement) uses a scalpel, scissors, or other instrument to cut necrotic tissue from a wound. It is the quickest and most efficient method of debridement. It is the preferred method if there is rapidly developing inflammation of the body's connective tissues (**cellulitis**) or a more generalized infection (sepsis) that has entered the bloodstream. The physician starts by flushing the area with a saline (salt water) solution, and then applies a topical anesthetic or analgesic gel to the edges of the wound to minimize **pain**. Using forceps to grip the dead tissue, the physician cuts it away bit by bit with a scalpel or scissors. Sometimes it is necessary to leave some dead tissue behind rather than disturb living tissue. The physician may repeat the process again at a later time.

A burn sufferer undergoes debridement (the removal of dead skin). The patterns on his chest are from skin grafts.

Mechanical debridement

In mechanical debridement, a saline-moistened dressing is allowed to dry overnight and adhere to the dead tissue. When the dressing is removed, the dead tissue is pulled away. This process is one of the oldest methods of debridement. It can be very painful because the dressing can adhere to living as well as nonliving tissue. Because mechanical debridement cannot select between good and bad tissue, it is an unacceptable debridement method for clean wounds where a new layer of healing cells is already developing.

Chemical debridement

Chemical debridement makes use of certain enzymes and other compounds to dissolve necrotic tissue. It is more selective than mechanical debridement. In fact, the body makes its own enzyme, collagenase, to break down collagen, one of the major building blocks of skin. A pharmaceutical version of collagenase is available and is highly effective as a debridement agent. As with other debridement techniques, the area first is flushed with saline. Any crust of dead tissue is etched in a crosshatched pattern to allow the enzyme to penetrate. A topical antibiotic is also applied to prevent introducing infection into the bloodstream. A moist dressing is then placed over the wound.

Autolytic debridement

Autolytic debridement takes advantage of the body's own ability to dissolve dead tissue. The key to the technique is keeping the wound moist, which can be accomplished with a variety of dressings. These dressings help to trap wound fluid that contains growth factors, enzymes, and immune cells that promote wound healing. Autolytic debridement is more selective than any other debridement method, but it also takes the longest to work. It is inappropriate for wounds that have become infected.

Biological debridement

Maggot therapy is a form of biological debridement known since antiquity. The larvae of *Lucilia sericata* (greenbottle fly) are applied to the wound as these organisms can digest necrotic tissue and

WWW.BOOKBAZ.IR

pathogenic bacteria. The method is rapid and selective, although patients are usually reluctant to submit to the procedure.

Preparation

Debridement is performed by physicians such as plastic surgeons, dermatologists, or surgeons, depending on the condition requiring the procedure. General physicians and surgeons are all trained in debridement techniques and usually perform debridement procedures. Nurses specializing in wound care are prepared to perform conservative sharp wound debridement once they have satisfactorily completed didactic and clinical instruction in the sharp debridement procedure from an accredited agency, wound management specialty course, or an approved course in debridement.

Surgical debridement is usually performed on an outpatient basis or at the bedside. If the target tissue is deep or close to another organ, however, or if the patient is experiencing extreme pain, the procedure may be done in an operating room.

The physician or nurse begins the process by assessing the need for debridement. The wound is examined, frequently by inserting a gloved finger into the wound to estimate the depth of dead tissue and evaluate whether it lies close to other organs, bone, or important body features. The assessment addresses the following points:

- the nature of the necrotic or ischemic tissue and the debridement procedure best suited to the wound
- the risk of spreading infection and the use of antibiotics
- the presence of underlying medical conditions causing the wound
- the extent of ischemia in the wound tissues
- the location of the wound in the body
- the type of pain management to be used during the procedure

Before surgical or mechanical debridement, the area may be flushed with a saline solution, and an analgesic cream or injection may be applied. If cream is used, it is usually applied over the exposed area some 90 minutes before the procedure.

Aftercare

After surgical debridement, the wound is usually packed with a dry dressing for a day to control bleeding. Afterward, moist dressings are applied to promote wound healing. Moist dressings are also used after mechanical, chemical, and autolytic debridement. Many factors contribute to wound healing, which frequently can take considerable time. Debridement may need to be repeated.

KEY TERMS

Abscess—A localized collection of pus buried in tissues or organs that may or may not discharge and usually results from an infectious process.

Analgesic—Medication that alleviates pain.

Eschar—A hardened dry crust that forms on skin exposed to burns or corrosive agents.

Gangrene—Death of tissue, usually in considerable mass and generally associated with loss of blood supply and followed by bacterial infection and decomposition.

Gas gangrene—A severe form of gangrene caused by *Clostridium* infection.

Ischemic—Tissue that has a low oxygen supply due to obstruction of the arterial blood supply or inadequate blood flow.

Necrotic—Affected with necrosis (cell death).

Pressure ulcer—Also known as a decubitus ulcer, pressure ulcers are open wounds that form whenever prolonged pressure is applied to skin covering bony outcrops of the body. Patients who are bedridden are at risk of developing pressure ulcers, commonly known as bedsores.

Sepsis—A severe systemic infection in which bacteria have entered the bloodstream.

Risks

It is possible that underlying tendons, blood vessels, or other structures may be damaged during the examination of the wound and during surgical debridement. Surface bacteria may also be introduced deeper into the body, causing infection.

Results

Removal of dead tissue from pressure **ulcers** and other wounds speeds healing. Although these procedures cause some pain, they are generally well tolerated by patients and can be managed more aggressively. It is not uncommon to debride a wound again in a subsequent session.

Alternatives

Adjunctive therapies include electrotherapy and low laser irradiation. However, insufficient research has been completed to recommend their general use.

Not all wounds need debridement. Sometimes it is better to leave a hardened crust of dead tissue (eschar) than to remove it and create an open wound, particularly if the crust is stable and the wound is not inflamed. Before performing debridement, the physician will take a medical history with attention to factors that might complicate healing, such as medications being taken and **smoking** status. The physician will also note the cause of the wound and the ways it has been treated. Some ulcers and other wounds occur in places where blood flow is impaired—for example, the foot ulcers that can accompany **diabetes mellitus**. In such cases, the physician or nurse may decide not to debride the wound, because blood flow may be insufficient for proper healing.

Decompression sickness

Definition

Decompression sickness (DCS) is a dangerous and occasionally lethal condition caused by nitrogen bubbles that form in the blood and other tissues of scuba divers who surface too quickly.

Description

According to the Divers Alert Network (DAN), a worldwide organization devoted to safe-diving research and promotion, less than 1% of divers fall victim to DCS or the rarer bubble problem called **gas embolism**, air **embolism**, or arterial gas embolism (AGE). A study of the United States military community in Okinawa, where tens of thousands of sport and military dives are made each year, identified 84 DCS and 10 AGE cases in 1989–95, including nine deaths. This translated into estimates of one case in every 7,400 dives and one death in every 76,900 dives.

WWW.BOOKBAZ.IR

DCS symptoms can be quite mild and many cases certainly go unnoticed by divers.

At times the terminology adopted by writers on DCS can be confusing. Some substitute the term decompression illness (DCI) for DCS. Others treat DCI as a label encompassing both DCS and AGE. An older term for DCS is caisson disease, coined in the nineteenth century when it was discovered that bridge construction crews working at the bottom of lakes and rivers in large pressurized enclosures (caissons) were experiencing joint **pain** (a typical DCS symptom) on returning to the surface.

Causes and symptoms

The air we breathe is mostly a mixture of two gases, nitrogen (78%) and oxygen (21%). Unlike oxygen, nitrogen is a biologically inert gas, meaning that it is not metabolized (converted into other substances) by the body. For this reason, most of the nitrogen we inhale is expelled when we exhale, but some is dissolved into the blood and other tissues. During a dive, however, the lungs take in more nitrogen than usual. This happens because the surrounding water pressure is greater than the air pressure at sea level (twice as great at 33 ft [10 m], for instance). As the water pressure increases, so does the pressure of the nitrogen in the compressed air inhaled by the diver. Because increased pressure causes an increase in gas density, the diver takes in more nitrogen with each breath than he or she would at sea level. Instead of being exhaled, however, the extra nitrogen safely dissolves into the tissues, where it remains until the diver begins his or her return to the surface (under some circumstances the extra nitrogen can cause **nitrogen narcosis**, but that condition is distinct from DCS). On the way up, decompression occurs (in other words, the water pressure drops), and with the change in pressure, the extra nitrogen gradually diffuses out of the tissues and is delivered by the bloodstream to the lungs, which expel it from the body. If the diver surfaces too quickly, however, potentially dangerous nitrogen bubbles can form in the tissues and cause DCS. These bubbles can compress nerves, obstruct arteries, veins, and lymphatic vessels, and trigger harmful chemical reactions in the blood. The precise reasons for bubble formation remain unclear.

How much extra nitrogen enters the tissues varies with the dive's depth and duration. Dive tables prepared by the U.S. Navy and other organizations specify how long most divers can safely remain at a particular depth. If the dive table limits are exceeded, the diver must pause on the way up to allow the nitrogen to diffuse into the bloodstream without forming bubbles; these pauses are called decompression stops, and are carefully calibrated. DCS can occur, however, even when a diver obeys safe diving rules. In such cases, the predisposing factors include **fatigue**, **obesity**, **dehydration**, **hypothermia**, and recent alcohol use. People who fly or travel to high-altitude locations without letting 12–24 hours pass after their last dive are at risk for DCS as well because their bodies undergo further decompression. This is true even when flying in commercial aircraft. Many travelers are unaware that to save money on fuel the cabin pressure in commercial aircraft is set much lower than the pressure at sea level. At 30,000 ft (9,144 m), for instance, cabin pressure is usually equivalent to the pressure at 7,000–8,000 ft (2,133–2,438 m) above sea level, a safe setting for everyone but recent divers. Exactly how long a diver should wait before flying or traveling to a high-altitude location depends on how much diving he or she has done and other considerations. If there is uncertainty about the appropriate waiting period, the sensible course of action is to let the full 24 hours pass.

Because the nitrogen bubbles that cause DCS can affect any of the body's tissues, including the blood, bones, nerves, and muscles, many kinds of symptoms are possible. Symptoms can appear minutes after a diver surfaces, and in about 80% of cases do so within eight hours. Pain is often the only symptom; this is sometimes called the bends, although many people incorrectly use that term as a synonym for DCS itself. The pain, which ranges from mild to severe, is usually limited to the joints, but can be felt anywhere. Severe **itching** (pruritis), skin **rashes**, and skin mottling (cutis marmorata) are other possible symptoms. All of these are sometimes classified as manifestations of type 1 or "mild" DCS. Type 2 or "serious" DCS can lead, among other things, to **paralysis**, brain damage, heart attacks, and death. Many DCS victims, however, experience both type 1 and type 2 symptoms.

Diagnosis

Diagnosis requires taking a medical history (questioning the patient about his or her health and recent activities) and conducting a **physical examination**.

Treatment

DCS is treated by giving the patient oxygen and placing him or her in a hyperbaric chamber, an enclosure in which the air pressure is first gradually increased and then gradually decreased. This shrinks the bubbles and allows the nitrogen to safely diffuse out of the tissues. Hyperbaric chamber facilities exist

KEY TERMS

Gas embolism—The presence of a gas bubble in the bloodstream that obstructs circulation.

Hyperbaric chamber—A sealed compartment in which air pressure is gradually increased and then gradually decreased, allowing nitrogen bubbles to shrink and the nitrogen to safely diffuse out of body tissue.

Lymphatic vessels—Vessels that carry a fluid called lymph from the tissues to the bloodstream.

Nitrogen narcosis—Also called "rapture of the deep," the condition is caused by increased nitrogen pressure at depth and is characterized by symptoms similar to alcohol intoxication.

throughout the United States. No matter how mild one's symptoms may appear, immediate transportation to a facility is essential. Treatment is necessary even if the symptoms clear up before the facility is reached, because bubbles may still be in the bloodstream and pose a threat. DAN maintains a list of facilities and a 24-hour hotline that can provide advice on handling DCS and other diving emergencies.

Prognosis

People with DCS who undergo chamber treatment within a few hours of symptom onset usually enjoy a full recovery. If treatment is delayed the consequences are less predictable, although many people have been helped even after several days have passed. A 1992 DAN report on diving accidents indicated that full recovery following chamber treatment was immediate for about 50% of divers. Some people, however, suffer numbness, tingling, or other symptoms that last weeks, months, or even a lifetime. In the Okinawa study, six of the 94 patients experienced "long-lasting" symptoms even after repeated chamber treatments.

Prevention

The obvious way to minimize the risk of falling victim to DCS is to follow the rules on safe diving and air travel after a dive. People who are obese, suffer from lung or heart problems, or are otherwise in poor health should not dive. Because the effect of nitrogen diffusion on the fetus remains unknown, diving while pregnant is not recommended.

Howard Baker

Decongestants

Definition

Decongestants are medicines used to relieve nasal congestion (stuffy nose).

Purpose

A congested or stuffy nose is a common symptom of colds and **allergies**. This congestion results when membranes lining the nose become swollen. Decongestants relieve the swelling by narrowing the blood vessels that supply the nose. This reduces the blood supply to the swollen membranes, causing the membranes to shrink.

These medicines do not cure colds or reverse the effects of histamines—chemicals released as part of the allergic reaction. They will not relieve all of the symptoms associated with colds and allergies, only the stuffiness.

When considering whether to use a decongestant for cold symptoms, keep in mind that most colds go away with or without treatment and that taking medicine is not the only way to relieve a stuffy nose. Drinking hot tea or broth or eating chicken soup may help. There are also adhesive strips can be placed on the nose to help widen the nasal passages, making breathing through the nasal passages a bit easier when congestion is present.

WWW.BOOKBAZ.IR

Precautions

Decongestant nasal sprays and nose drops may cause a problem called rebound congestion if used repeatedly over several days. When this happens, the nose remains stuffy or gets worse with every dose. The only way to stop the cycle is to stop using the drug. The stuffiness should then go away within about a week. Anyone who shows signs of severe rebound congestion should also contact his or her physician.

Do not use decongestant nasal sprays for more than three days. Decongestants taken by mouth should not be used for more than seven days. If the congestion has not gone away in this time, or if the symptoms are accompanied by **fever**, call a physician.

Do not use a decongestant nasal spray after the product's expiration date. If the product has become cloudy or discolored, throw it away and do not use it. Do not share droppers or spray bottles with anyone else, as this could spread infection. Do not let droppers and bottle tips touch countertops or other surfaces.

Some decongestants cause drowsiness. People who takes these drugs should not drive, use machines or do anything else that might be dangerous until they have found out how the drugs affect them.

In general, older people may be more sensitive to the effects of decongestants and may need to take lower doses to avoid side effects. People in this age group should not take long-acting (extended release) forms of decongestants unless they have previously taken a short-acting form with no ill effects.

Children may also be more sensitive to the effects of decongestants. Before giving any decongestant to a child, check the package label carefully. Some of these medicines are too strong for use in children. Serious side effects are possible if they are given large amounts of these drugs or if they swallow nose drops, nasal spray or eye drops. If this happens, call a physician or poison center immediately.

Special conditions

People with certain medical conditions or who are taking certain other medicines can have problems if they take decongestants. Before taking these drugs, be sure to let the physician know about any of these conditions:

ALLERGIES. Anyone who has had unusual reactions to decongestants in the past should let his or her physician know before these drugs or any similar drugs are prescribed. The physician should also be told about any allergies to foods, dyes, preservatives, or other substances.

PREGNANCY. In studies of laboratory animals, some decongestants have had unwanted effects on fetuses. However, it is not known whether such effects also occur in people. Women who are pregnant or who plan to become pregnant should check with their physicians before taking decongestants.

BREASTFEEDING. Some decongestants pass into breast milk and may have unwanted effects on nursing babies whose mothers take the drugs. Women who are **breastfeeding** should check with their physicians before using decongestants. If they need to take the medicine, it may be necessary to bottle feed the baby with formula while taking it.

OTHER MEDICAL CONDITIONS. Anyone with heart or blood vessel disease, high blood pressure, diabetes, **enlarged prostate**, or overactive thyroid should not take decongestants unless under a physician's supervision. The medicine can increase blood sugar in people with diabetes. It can be especially dangerous in people with high blood pressure, as it may increase blood pressure.

Before using decongestants, people with any of these medical problems should make sure their physicians are aware of their conditions:

- glaucoma
- history of mental illness

Decongestants may have a variety of side effects, and may also interact with other medications the patient is taking.

Side effects

DECONGESTANT NASAL SPRAYS AND NOSE DROPS. The most common side effects from decongestant nasal sprays and nose drops are sneezing and temporary burning, stinging, or dryness. These effects are usually temporary and do not need medical attention. If any of the following side effects occur after using a decongestant nasal spray or nose drops, stop using the medicine immediately and call the physician:

- increased blood pressure
- headache
- fast, slow, or fluttery heartbeat
- nervousness
- dizziness
- nausea
- sleep problems

DECONGESTANTS TAKEN BY MOUTH. The most common side effects of decongestants taken by mouth are nervousness, restlessness, excitability, **dizziness**, drowsiness, **headache**, nausea, weakness, and

sleep problems. Anyone who has these symptoms while taking decongestants should stop taking them immediately.

Patients who have these symptoms while taking decongestants should call the physician immediately:

- increased blood pressure
- fast, irregular, or fluttery heartbeat
- severe headache
- tightness or discomfort in the chest
- breathing problems
- fear or anxiety
- hallucinations
- trembling or shaking
- convulsions (seizures)
- pale skin
- painful or difficult urination

Other side effects may occur. Anyone who has unusual symptoms after taking a decongestant should get in touch with his or her physician.

Interactions with other medicines

Decongestants may interact with a variety of other medicines. When this happens, the effects of one or both of the drugs may change or the risk of side effects may be greater. Do not take decongestants at the same time as these drugs:

- Monoamine oxidase inhibitors (MAO inhibitors) such as phenzeline (Nardil) or tranylcypromine (Parnate), used to treat conditions including depression and **Parkinson's disease**. Do not take decongestants at the same time as a MAO inhibitor or within two weeks of stopping treatment with an MAO inhibitor unless a physician approves.
- Other products containing the same or other decongestants.
- Caffeine.

In addition, anyone who takes decongestants should let the physician know all other medicines he or she is taking. Among the drugs that may interact with decongestants are:

- tricyclic antidepressants such as imipramine (Tofranil) or desipramine (Norpramin)
- the antidepressant maprotiline (Ludiomil)
- amantadine (Symmetrel)
- amphetamines
- medicine to relieve asthma or other breathing problems
- methylphenidate (Ritalin)

KEY TERMS

Fetus—A developing baby inside the womb.

Hallucination—A false or distorted perception of objects, sounds, or events that seems real. Hallucinations usually result from drugs or mental disorders.

- appetite suppressants
- other medicine for colds, sinus problems, hay fever or other allergies
- beta-blockers such as atenolol (Tenormin) and propranolol (Inderal)
- digitalis glycosides, used to treat heart conditions

Be sure to check with a physician or pharmacist before combining decongestants with any other prescription or nonprescription (over-the-counter) medicine.

Description

Decongestants are sold in many forms, including tablets, capsules, caplets, gelcaps, liqui-caps, liquids, nasal sprays, and nose drops. These drugs are sometimes combined with other medicines in cold and allergy products designed to relieve several symptoms. Some decongestant products require a physician's prescription, but there are also many nonprescription (over-the-counter) products. Ask a physician or pharmacist about choosing an appropriate decongestant.

Commonly used decongestants include oxymetazoline (Afrin and other brands) and pseudoephedrine (Sudafed, Actifed, and other brands). The decongestant oxymetazoline is also used in some eye drops to relieve redness and **itching**.

The recommended dosage depends on the drug. Check with the physician who prescribed the drug or the pharmacist who filled the prescription for the correct dosage, and always take the medicine exactly as directed. If using nonprescription (over-the-counter) types, follow the directions on the package label or ask a pharmacist for assistance. Never take larger or more frequent doses, and do not take the drug for longer than directed.

Risks

Anyone considering taking a decongestant should take a close look at the labels of any already in their

WWW.BOOKBAZ.IR

medicine cabinet. In 2000, the Food and Drug Administration prohibited over-the-counter sales of medicines containing the decongestant phenylpropanolamine. The medicine is associated with an increased risk of **stroke** in people ages 18 to 49, especially women. Many cold remedies contained this medicine. Contact a pharmacist if there is any question about the ingredients in a medication. Over-the-counter remedies containing phenylpropanolamine should be discarded.

Results

The desired result when taking decongestants is the short-term relief of nasal congestion.

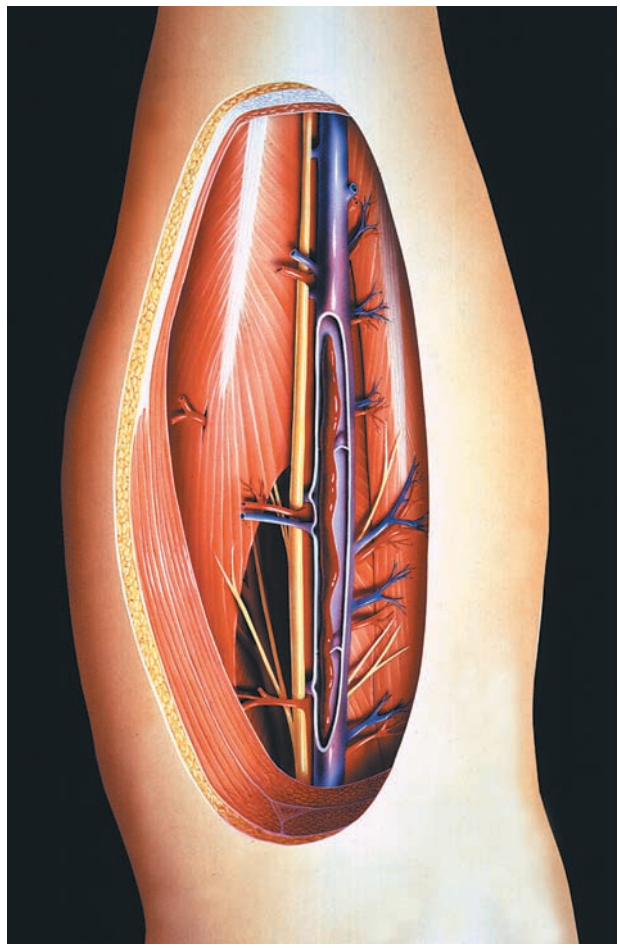
Deep vein thrombosis

Definition

Deep vein thrombosis (DVT) is a blood clot in a major vein that usually develops in the legs and/or pelvis.

Description

Deep vein thrombosis is a common but difficult to detect illness that can be fatal if not treated effectively. The disorder is estimated to affect 80 people per 100,000 population annually, but some experts feel this is an underestimate of the disorder because the condition often remains undetected and resolves on its on without complications. About 600,000 people are hospitalized in the United States for DVT each year. If left untreated, DVT can cause pulmonary emboli. This is a potentially fatal complication in which **blood clots** break off, travel through the circulatory system, and become lodged in and block an artery going to the lungs. Each year about 200,000 people die of pulmonary emboli caused by DVT. Deep vein thrombosis is also called venous thromboembolism, **thrombophlebitis** or phlebothrombosis.



This illustration features a dissected human lower leg showing clot formation (thrombosis) along the length of a vein. *(Custom Medical Stock Photo, Inc.)*

Deep vein thrombosis is a major complication in patients who have had **orthopedic surgery** or pelvic, abdominal, or **thoracic surgery**. Patients with cancer and other chronic illnesses (including **congestive heart failure**), as well as those who have experienced a recent **heart attack** (myocardial infarction), are also at high risk for developing DVT. Deep vein thrombosis can be chronic, with recurrent episodes.

Causes and symptoms

Deep vein thrombosis is caused by blood clots in blood vessels that form in veins where blood flow is sluggish or has been disturbed, in pockets in the deep veins of the calf, or in veins that have been traumatized. Symptoms include swelling and tenderness, **pain** in the calf or thigh, and possibly warmth. Fewer than half of all people with the condition

KEY TERMS

Catheter—A long, thin, flexible tube that can be inserted into a vein and moved through the cardiovascular system.

Pulmonary embolism—An obstruction of a blood vessel in the lungs, usually caused by a blood clot that blocks a coronary artery. Pulmonary embolism can be very serious and, in some cases, fatal.

Thrombosis—The development of a blood clot inside a blood vessel.

experience symptoms, and symptoms tend to be nonspecific (e.g., leg pain may be caused by many other conditions). Some individuals and families have underlying clotting tendencies that can be tested for.

Diagnosis

Deep vein thrombosis can be detected through **venography** and radionuclide venography, **Doppler ultrasonography**, and impedance plethysmography. Venography is the most accurate test, but it is not used much because it is often painful, expensive, exposes the patient to radiation, and can cause allergic reactions and complications. Venography identifies the location, extent, and degree of attachment of the blood clots and enables the condition of the deep leg veins to be assessed. A contrast solution is injected into a foot vein through a catheter. The physician observes the movement of the solution through the vein with a fluoroscope while a series of x rays are taken. Venography takes 30–45 minutes and can be done in a physician's office, a laboratory, or a hospital. Radionuclide venography, in which a radioactive isotope is injected, is occasionally used, especially if a patient has had an allergic reaction to contrast solutions.

Doppler ultrasonography usually is the preferred procedure for detecting deep vein thrombosis. This technique uses sound waves to measure blood flow through leg veins and arteries. A blood pressure cuff is wrapped around the patient's ankle and a transducer with gel on it is placed over pulse points of the foot and lower leg. High-frequency sound waves bounce off the soft tissue, and the echoes are converted into images on a monitor. This procedure is very accurate in detecting clots above the knee that can become pulmonary embolisms. Usually performed in a physician's office or hospital outpatient diagnostic center, Doppler **ultrasound** takes about 30–45 minutes.

Impedance plethysmography is a noninvasive way to record changes in blood volume and vessel resistance. A blood pressure cuff is wrapped around the leg above the knee, four electrodes are placed near the knee and the ankle, and the cuff is inflated to compress the veins and reduce blood flow. The efficiency with which the veins return to normal is then measured. Performed in a physician's office, impedance plethysmography takes about 15 minutes.

Treatment

Deep vein thrombosis can be treated with drug therapy, bed rest, and gradient elastic stockings. Medications include anticoagulants that "thin" blood to prevent further growth of blood clots, as well as clot-dissolving drugs. Heparin is a common injectable anticoagulant and is usually followed by warfarin (Coumadin) tablets for at least three months. Bed rest with the patient's legs elevated is necessary until the condition improves. Gradient elastic stockings should then be worn, and standing for long periods avoided. In some cases, a filter is surgically placed in the major vein (the inferior vena cava) to trap emboli or clots before they get to the heart and lungs. In another surgical procedure, a catheter is inserted into the vein. When the clot is reached, a balloon at the end of the catheter is inflated, and then withdrawn along with the clot. However, this procedure risks dislodging the clot.

Alternatives

Deep vein thrombosis can be life threatening and must be treated with conventional medical therapies. However, some alternative therapies may be used in conjunction with conventional treatments to dissolve the clot. These therapies may help support the body and prevent recurrence. A conventional physician as well as a trained alternative health care practitioner should be consulted due to the severity of this condition.

Prognosis

Complications from DVT can be life threatening or chronically debilitating. Pulmonary emboli develop in about 10% of people with DVT and account for about 10% of all hospital deaths. DVT also can cause inflammation of the blood vessels resulting in loss of contractility and chronically decreased function. On the other hand, about three-quarters of people with DVT remain free of symptoms, and in many cases, the condition resolves with minimal treatment.

WWW.BOOKBAZ.IR

Prevention

Deep vein thrombosis can be prevented through prophylactic **anticoagulant drugs** and venous stasis prevention with gradient elastic stockings and intermittent pneumatic compression of the legs. Individuals should avoid standing or sitting for long periods without moving; walking or exercising the legs on long airplane and car trips helps keep blood from pooling in the legs and helps to prevent DVT. High-risk individuals often need to remain on oral anticoagulants (e.g., Coumadin) indefinitely.

Deer-fly fever *see* **Tularemia**

Defibrillation

Definition

Defibrillation is a process in which an electrical device called a defibrillator sends an electric **shock** to the heart to stop an arrhythmia (irregular heartbeat), resulting in the return of a productive heart rhythm.

Defibrillation by paddles. *(Custom Medical Stock Photo, Inc.)*

Purpose

Defibrillation is performed to correct life-threatening **arrhythmias** of the heart, including **ventricular fibrillation** and cardiac arrest. In cardiac emergencies, it should be performed immediately after identifying that the patient is experiencing an arrhythmia, indicated by unresponsiveness and lack of a pulse. If an electrocardiogram is available, the arrhythmia can be displayed visually for additional confirmation. In non-life-threatening situations, a physician can use atrial defibrillation to treat **atrial fibrillation** or flutter.

Description

Cardiac arrhythmias that prevent the heart from pumping blood to the body can cause irreversible damage to the major organs, including the brain and heart. These arrhythmias include **ventricular tachycardia**, fibrillation, and cardiac arrest. About 10% of the ability to restart the heart is lost with every minute that the heart fibrillates. Death can occur in minutes unless a productive heart rhythm that is able to generate a pulse is restored through defibrillation. Because immediate defibrillation is crucial to the patient's survival, the American Heart Association has called for the integration of defibrillation into an effective emergency cardiac care system. The system should include early access, early **cardiopulmonary resuscitation**, early defibrillation, and early advanced cardiac care.

Defibrillators deliver a brief electric shock to the heart, which enables the heart's natural pacemaker to regain control and establish a productive heart rhythm. The defibrillator is an electronic device that includes defibrillator paddles and electrocardiogram monitoring.

During external defibrillation, the paddles are placed on the patient's chest, along with a conducting gel to ensure good contact with the skin. When the heart can be visualized directly, such as during **thoracic surgery**, sterile internal paddles are applied directly to the heart. Direct contact with the patient is discontinued. If additional defibrillation is required, the paddles should be repositioned exactly to increase the likelihood of further shocks being effective in stopping the arrhythmia. The patient's pulse and/or electrocardiogram are continually monitored when defibrillation is not in progress. Medications to treat possible causes of the abnormal heart rhythm may be administered. Defibrillation continues until the patient's condition stabilizes or the procedure is ordered to be discontinued.

Early defibrillators, about the size and weight of a car battery, were used primarily in ambulances and hospitals. The American Heart Association now advocates public access defibrillation; this calls for placing automated external defibrillators (AEDS) in places like police vehicles, airplanes, and at public events. The AEDS are smaller, lighter, less expensive, and easier to use than the early defibrillators. They are computerized to provide simple, verbal instructions to the operator and to make it impossible to deliver a shock to a patient whose heart is not fibrillating.

Precautions

Defibrillation should not be performed on a patient who has a pulse or is alert, as this could cause a lethal heart rhythm disturbance or cardiac arrest. The paddles used in the procedure should not be placed on a woman's breasts or over an internal pacemaker.

Preparation

Once a patient is found in cardiac distress—without a pulse and non-responsive—and help is summoned, cardiopulmonary resuscitation (CPR) is begun and continued until the medical team arrives and is able to provide defibrillation. Electrocardiogram leads are attached to the patient's chest. Gel or paste is applied to the defibrillator paddles, or two gel pads are placed on the patient's chest. The response team verifies the patient's lack of a pulse while visualizing the electrocardiogram, assures that contact with the patient is discontinued, and delivers the electrical charge.

Atrial defibrillation is a treatment option that is ordered for atrial fibrillation or flutter. The electrocardiogram is monitored throughout the procedure. The paddles are placed on the patients chest with conducting gel to ensure good contact between the paddles and skin. If the heart can be visualized directly during thoracic surgery, the paddles will be applied directly to the heart. The defibrillator is programmed to recognize distinct components of the electrocardiogram and will only fire the electrical shock at the correct time. Again, all direct contact with the patient is discontinued prior to defibrillation.

KEY TERMS

Arrhythmia—A cardiac rhythm different then normal sinus rhythm with a rate outside of the range of 60–120 beats per minute for an adult patient.

Cardiac arrest—A condition in which the heart has no discernable electrical activity to stimulate contraction, therefore no blood is pumped.

Fibrillation—Very independent rapid contraction of cardiac muscle fibers producing no productive contraction, therefore no blood is pumped.

Intubation—Placing a tube into the lungs through the trachea to provide forced respiration.

Pacemaker—A surgically implanted electronic device that sends out electrical impulses to regulate a slow or erratic heartbeat.

Aftercare

After defibrillation, the patient's cardiac status, breathing, and vital signs are monitored with a cardiac monitor. Additional tests to measure cardiac damage will be performed, which can include a 12-lead electrocardiogram, a **chest x-ray**, and **cardiac catheterization**. Treatment options will be determined from the outcome of these procedures. The patient's skin is cleansed to remove gel and, if necessary, electrical **burns** are treated.

Risks

Skin burns from the defibrillator paddles are the most common complication of defibrillation. Other risks include injury to the heart muscle, abnormal heart rhythms, and **blood clots**.

Results

Defibrillation performed to treat life-threatening ventricular arrhythmias is most likely to be effective within the first five minutes, preventing brain injury and death by returning the heart to a productive rhythm able to produce a pulse. Patients will be transferred to a hospital critical care unit for additional monitoring, diagnosis, and treatment of the

WWW.BOOKBAZ.IR

arrhythmia. Intubation may be required for respiratory distress. Medications to improve cardiac function and prevent additional arrhythmias, are frequently administered. Some cardiac function may be lost due to the actual defibrillation, but loss is also associated with the underlying disease.

The goal of atrial defibrillation is restoring cardiac output, alleviating **shortness of breath**, and decreasing the occurrence of clot formation in the atria.

Dehydration

Definition

Dehydration is a condition in which the body loses too much water, usually as a result of excess sweating, **vomiting**, and/or **diarrhea**.

Description

Dehydration occurs because more fluid is lost from the body than is taken in. Water is essential for life. Transporting nutrients throughout the body, removing wastes, regulating body temperature, lubrication of joints and membranes, and chemical reactions that occur during cellular metabolism all require water.

The amount of water a person needs to prevent dehydration varies widely depending on the individual's age, weight, level of physical activity, and the environmental temperature. The individual's health and the medications they take may also affect the amount of water a person needs. Most dehydration results from an acute, or sudden, loss of fluids. However, slow-developing chronic dehydration can occur, most often in the frail elderly and in infants and young children, who must rely on others to supply them with liquids.

Healthy people lose water from urination, elimination of solid wastes, sweating, and breathing out water vapor. This water must be replaced through diet. Water makes up about 75% of the body weight of infants, 65% of the weight of children, and 60% of the weight of an adult. In 2004, the United States Institute of Medicine (IOM) recommended that relatively inactive adult men take in about 3.7 L (about 15 cups) of fluids daily and that women take in about of 2.7 L (about 10 cups) to replace lost water. These recommendations are for total fluid intake from both beverages and food. Highly active adults, **breastfeeding** women, and those living in very warm climates need more fluids.

About 80% of the water the average person needs is replaced by drinking liquids. The other 20% is found in food. Below are some foods and the percentage of water that they contain:

- iceberg lettuce, 96%
- squash, cooked, 90%

- cantaloupe, raw, 90%
- 2% milk, 89%
- apple, raw, 86%
- cottage cheese, 76%
- potato, baked, 75%
- macaroni, cooked, 66%
- turkey, roasted, 62%
- steak, cooked, 50%
- cheese, cheddar, 37%
- bread, white, 36%
- peanuts, dry roasted, 2%

Dehydration involves more than just water deficiency. Electrolytes are ions that form when salts dissolve in water or body fluids. In order for cells to function correctly, the various electrolytes, such as **sodium** (Na^+) and potassium (K^+), must remain within a very narrow range of concentrations. Often electrolytes are lost along with water. For example, sodium is lost in sweat. To prevent the effects of dehydration, both water and electrolytes must be replaced in the correct proportions.

Demographics

The very young and the very old are most likely to become dehydrated. Young children are at greater risk because they are more likely to get diseases that cause vomiting, diarrhea, and **fever**. Worldwide, dehydration (secondary to diarrheal disease) is the leading cause of death in children. In the United States, 400–500 children under the age of five die every year of dehydration. The elderly are at risk because they are less likely to drink when they become dehydrated. The thirst mechanism often becomes less sensitive as people age. Also, their kidneys lose the ability to make highly concentrated urine. Older individuals who are confined to wheelchairs or bed and cannot get water for themselves (e.g., nursing home and hospital patients) are at risk of developing chronic dehydration.

Causes and symptoms

Diarrhea, often accompanied by vomiting, is the leading cause of dehydration. Both water and electrolytes are lost in large quantities. Diarrhea is often caused by bacteria, viruses, or parasites. Fever that often accompanies disease accelerates the amount of water that is lost through the skin. The smaller the child, the greater the risk of dehydration. Worldwide, acute diarrhea accounts for the death of about four million children each year. In the United States, about 220,000 children are hospitalized for dehydration caused by diarrhea annually.

Heavy sweating also causes dehydration and loss of electrolytes. Athletes, especially endurance athletes, and individuals with active outdoor professions such as roofers and road crew workers are at high risk of becoming dehydrated. Children who play sports can also be vulnerable to dehydration.

Certain chronic illnesses that disrupt fluid balance can cause dehydration. **Kidney disease** and hormonal disorders, such as diabetes, adrenal gland, or pituitary gland disorders, can cause fluid and electrolyte loss through excessive urination. Disorders such as **cystic fibrosis** or other genetic disorders resulting in inadequate absorption of nutrients from the intestines can cause chronic diarrhea that leads to dehydration. Individuals with **eating disorders** who abuse **laxatives**, **diuretics**, and **enemas**, or regularly cause themselves to vomit are vulnerable to severe electrolyte imbalances and dehydration. The same is true of people with **alcoholism**. People who have severe **burns** over a large part of their body also are likely to become dehydrated because they no longer have skin to act as a barrier to evaporation.

Dehydration can be mild, moderate, or severe. Mild dehydration occurs when fluid losses equal 3–5%. At this point, the thirst sensation is felt and is often accompanied by **dry mouth** and thick saliva.

Moderate dehydration occurs when fluid losses equal 6–9% of body weight. This can occur rapidly in young children who are vomiting and/or have diarrhea. In an infant, a loss of as little as 2–3 cups of liquids can result in moderate dehydration. Signs of moderate dehydration include intense thirst, severely reduced urine production, sunken eyes, **headache**, **dizziness**, irritability, and decreased activity.

Severe dehydration occurs when fluid losses are 10% or more of body weight. Severe dehydration is a medical emergency for individuals of any age. A loss of fluids equalling 20% of a person's body weight is fatal. Signs of severe dehydration include all those of moderate dehydration as well as lack of sweating, little or no urine production, dry skin that has little elasticity, low blood pressure, rapid heartbeat, fever, **delirium**, or **coma**.

Diagnosis

Dehydration is diagnosed by physical symptoms. A healthcare professional or observant adult can usually tell by looking at someone that they are moderately or severely dehydrated. Blood tests and a **urinalysis** may be done to check for electrolyte imbalances and

WWW.BOOKBAZ.IR

to determine if the kidneys are damaged. However, visual signs are enough to begin treatment.

Treatment

The goal of treatment is to restore fluid and electrolyte balance. For individuals with mild dehydration, this can be done in infants and children by giving them oral rehydration solutions such as Pedialyte, Infalyte, Naturalyte, Oralyte, or Rehydralyte. These are available in supermarkets and pharmacies without a prescription. These solutions have the proper balance of salts and sugars to restore the electrolyte balance. Water, apple juice, chicken broth, sodas, and similar fluids are effective in treating mild dehydration. Oral rehydration fluids can be given to young children in small sips as soon as vomiting and diarrhea start. They may continue to vomit and have diarrhea, but some of the fluid will be absorbed. Breastfed infants should continue to nurse on demand. Babies who are formula fed should continue to get their regular formula unless directed otherwise by a pediatrician.

Older children who are dehydrated can be given oral rehydration solutions or sports drinks such as Gatorade for moderate and severe dehydration, otherwise general fluids are fine. Athletes who are dehydrated should be given sports drinks. According to the American College of Sports Medicine, sports drinks are effective in supplying energy for muscles, maintaining blood sugar levels, preventing dehydration, and replacing electrolytes lost in sweat. Adults who are mildly or moderately dehydrated usually improve by drinking water and avoiding coffee, tea, and soft drinks that do not contain **caffeine**.

Individuals of all ages who are seriously dehydrated need to be treated by a medical professional. In the case of severe dehydration, the individual may be hospitalized and fluids given intravenously (IV; directly into the vein).

Dehydration is usually an acute condition, and once fluid balance is restored, there are no additional nutritional concerns. In the mobility-impaired elderly, the main concern is making sure that they have adequate access to fluids.

Prognosis

Most people recover from dehydration with few complications so long as rehydration fluids are available and treatment begins before the condition becomes severe. However, severe dehydration can be fatal.

KEY TERMS

Diabetes—A condition in which the body either does not make or cannot respond to the hormone insulin. As a result, the body cannot use glucose (sugar). There are two types, type 1 and type 2.

Diuretic—A substance that removes water from the body by increasing urine production.

Electrolyte—Ions in the body that participate in metabolic reactions. The major human electrolytes are sodium (Na^+), potassium (K^+), calcium (Ca^{2+}), magnesium (Mg^{2+}), chloride (Cl^-), phosphate (HPO_4^{2-}), bicarbonate (HCO^{3-}), and sulfate (SO_4^{2-}).

Laxative—A substance that stimulates movement of food through the bowels. Laxatives are used to treat constipation.

Prevention

The best way to prevent dehydration is to be alert to situations in which it could occur, such as exercising in hot weather or vomiting and diarrhea in infants and young children. Athletes, people who work in hot conditions, and children should drink regularly, whether or not they feel thirsty. A healthcare provider should be consulted before the situation becomes serious. Mobility-impaired elderly and infants and young children who cannot get water for themselves should be offered fluids on a regular basis.

Delayed hypersensitivity skin test

Definition

A delayed hypersensitivity test (DHT) is an immune function test measuring the presence of activated T cells that recognize a certain substance.

Purpose

The immune system protects against infection by viruses, bacteria, fungi, and parasites. After initial exposure to a foreign substance, or antigen, the immune system creates both antibodies and sensitized T cells. Both these immune agents respond when the body is reexposed to the antigen. Antibodies, which are circulating proteins, respond within minutes, to give what, is termed an immediate hypersensitivity reaction. T cells responses occur over several days, and are thus called delayed hypersensitivity reactions. The cascade of events initiated by the T cells leads to hardening (induration) and redness (erythema) at the injection site.

A DHT is performed for one of three reasons:

- To test for exposure to specific diseases, such as tuberculosis (TB). Tuberculosis testing is done by injecting into the skin a small volume of TB antigen, which contains no organisms (live or dead) but can still provoke an immune response.
- To test for allergic sensitivity to potential skin irritants, such as poison ivy. Skin allergy testing is usually done by placing a series of adhesive patches on the skin containing potential allergens, or allergy-causing substances.
- To assess the vitality of the T cell response as part of the evaluation of immune system health in infection, cancer, immune disorders, pre-transplantation screening, aging, and malnutrition. DHT can help predict survival in immunocompromised patients, and evaluate the success of restorative therapy. Antigens used for these tests must be ones the patient has been exposed to before, and, therefore, include inactivated antigens from common infectious agents to which the patient might have been exposed, such as mumps, *Candida albicans*, tetanus toxoid, and trichophyton (a skin fungus).

Precautions

No special precautions are necessary for most patients. Those with known hypersensitivity to certain skin irritants should alert the clinician performing the test. Some commercial preparations of fungal antigens contain mercury, a source of irritation to some patients.

Description

The most accurate TB test is the Mantoux test, in which a small amount of TB antigen is injected into the skin. The area is examined 48–72 hours after the injection.

In the patch test, 20–30 adhesive patches are usually placed on the upper back. The patches are kept in place and the area is kept dry for 48 hours. The patches are then removed, and the skin is examined 24 hours afterward, and possibly again a day or more following that. Patch testing is usually performed following a patient complaint of skin irritation from an unknown substance. Testing may suggest several candidates; identifying the right one requires careful review of the patient's possible exposure.

The test of overall T cell responsiveness is performed with several injections. Each area injected is circled and marked. Results are read 48 hours after the injection.

Preparation

No special preparation is necessary.

WWW.BOOKBAZ.IR

KEY TERMS

Allergen—A foreign substance that provokes an immune reaction in some sensitive people but not in most others.

Anaphylaxis—An exaggerated, life-threatening hypersensitivity reaction to a previously encountered antigen.

Antibody—An immune system protein made to fight infection.

Antigen—A foreign substance detected that provokes an immune reaction.

Aftercare

Patches should be kept dry. Injection sites may be washed, but excessive rubbing should be avoided. Patches and injection sites may become reddened or irritated. If a patch causes severe **itching** or discomfort, the patient should remove it immediately.

Risks

DHT is quite safe for virtually all people. There is no risk of infection from the agents injected, since they are purified antigens, not whole organisms. Life threatening, hypersensitive reactions (**anaphylaxis**) are a very small risk; patients should notify the administering physician immediately if signs of **wheezing**, swelling, or diffuse redness of the skin develops.

Results

Absence of exposure to TB is indicated by absent or very little skin reaction; redness or hardness smaller than about 0.25 in (5 mm) is considered normal for a person not exposed or infected with TB.

Patch test sites should be normal or only slightly red.

T cell responsiveness tests should be positive; that is, the injected areas should be reddened and hard. Two affected areas of 0.2 in (2 mm) or more is considered a positive result.

Abnormal results

TB exposure is indicated by a reaction of 10 mm or more. The degree of redness is not important. A 0.25–0.5 in (5–10 mm) area could indicate exposure if there is an underlying risk to TB.

Patch test areas that become reddened and irritated indicate reaction to the substance in the patch.

Absence of any reaction to injected areas indicates lack of T cell responsiveness, a condition called anergy. T cell anergy is seen in immune deficiency diseases including **AIDS**, some cases of infectious diseases, malignancies, immunosuppressive therapy (including corticosteroid treatment), some autoimmune diseases, **malnutrition**, major surgery, and some viral immunizations.

Delirium

Definition

Delirium is a neurocognitive disorder characterized by a state of mental confusion that develops quickly, usually fluctuates in intensity, and is usually reversible.

Description

Delirium is a syndrome, or group of symptoms, caused by a disturbance in the normal functioning of the brain. The delirious patient has a reduced awareness of and responsiveness to the environment, which may be manifested as disorientation, incoherence, and memory disturbance. Delirium is often marked by **hallucinations**, **delusions**, and a dream-like state.

Demographics

Although delirium can occur in individuals of any age, it is most common in the elderly and is a part of many terminal illnesses. The *Diagnostic and Statistical Manual of Mental Disorders (DSM-5)* estimates that between 25% and 56% of people who have just had surgery experience delirium. In addition 70–80% of those in intensive care units, and 60% of those in nursing homes have periods of delirium as do up to 2% of non-institutionalized individuals living in the community.

Causes and symptoms

Causes

There are a large number of possible causes of delirium. Metabolic disorders are the single most common cause, accounting for 20–40% of all cases. This type of delirium, termed "metabolic encephalopathy," may result from organ failure, including liver or kidney failure. Other metabolic causes include **diabetes mellitus**, **hyperthyroidism** and **hypothyroidism**, vitamin deficiencies, and imbalances of fluids and electrolytes in the blood. Severe **dehydration** can also cause delirium.

Drug intoxication (intoxication confusional state) is responsible for up to 20% of delirium cases, either from side effects, overdose, or deliberate ingestion of a mind-altering substance. Medicinal drugs with delirium as a possible side effect or result of overdose include:

- anticholinergics, including atropine, scopolamine, chlorpromazine (an antipsychotic), and diphenhydramine (an antihistamine)
- sedatives, including barbiturates, benzodiazepines, and ethanol (drinking alcohol)
- antidepressant drugs
- anticonvulsant drugs
- nonsteroidal anti-inflammatory drugs (NSAIDs), including ibuprofen and acetaminophen
- corticosteroids, including prednisone
- anticancer drugs, including methotrexate and procarbazine
- lithium
- cimetidine
- antibiotics
- L-dopa

Delirium may result from ingestion of legal or illegal psychoactive drugs, such as:

- ethanol (drinking alcohol)
- marijuana
- LSD (lysergic acid diethylamide) and other hallucinogens
- amphetamines
- cocaine
- opiates, including heroin and morphine
- PCP (phencyclidine)
- inhalants

Drug withdrawal may cause delirium. Delirium tremens (DTs) may occur during alcohol withdrawal after prolonged or intense consumption. Withdrawal symptoms are possible from many of the psychoactive prescription and street drugs as well.

Poisons may cause delirium (toxic **encephalopathy**), including:

- solvents, such as gasoline, kerosene, turpentine, benzene, and alcohols
- carbon monoxide
- refrigerants (Freon)
- heavy metals, such as lead, mercury, and arsenic
- insecticides, such as Parathion and Sevin
- mushrooms, such as *Amanita* species
- plants such as jimsonweed (*Datura stramonium*) and morning glory (*Ipomoea* spp.)
- animal venoms

Other causes of delirium include:

- infection
- fever
- head trauma
- epilepsy
- brain hemorrhage or infarction
- brain tumor
- low blood oxygen (hypoxemia)
- high blood carbon dioxide (hypercapnia)
- post-surgical complication

Delirium can also be classified as hyperactive (shouting, moving constantly), hypoactive (quiet, compliant), or mixed level of activity.

Symptoms

The symptoms of delirium come on quickly, in hours or days, in contrast to those of **dementia**, which develop much more slowly. Delirium symptoms typically fluctuate through the day, with periods of relative calm and lucidity alternating with periods of florid delirium. Symptoms often worsen in the evening, a condition sometimes called "sundowner syndrome." The hallmark of delirium is a fluctuating level of consciousness. Symptoms may include:

- decreased awareness of the environment
- confusion or disorientation, especially of time
- memory impairment, especially of recent events
- hallucinations
- illusions and misinterpreted stimuli
- increased or decreased activity level
- mood disturbance, possibly including anxiety, euphoria or depression
- language or speech impairment

WWW.BOOKBAZ.IR

KEY TERMS

Dementia—A loss of mental ability severe enough to interfere with functioning. While dementia and delirium have some of the same symptoms, dementia has a much slower onset.

Electroencephalogram (EEG)—A chart of the brain wave patterns picked up by electrodes placed on the scalp. This is useful for diagnosing central nervous system disorders.

Encephalopathy—A brain dysfunction or disorder.

Diagnosis

Delirium is diagnosed through the medical history and recognition of symptoms during mental status examination. The most important part of diagnosis is determining the cause of the delirium.

The *DSM-5* lists five criteria that must be met to diagnose delirium. These are:

- A disturbance in attention and awareness.
- Development of symptoms over a short period with symptoms of fluctuating intensity.
- In addition to disturbance in attention and awareness, there must be a disturbance in at least one of the following: memory, orientation, language, perception.
- The disturbances cannot be explained by another mental disorder.
- Delirium must arise as the result of a physiological occurrence such as another medical condition or illness, substance intoxication, or poisoning.

Tests

Tests are done to determine the cause of the delirium. These tests may include blood and urine analysis for levels of drugs, fluids, electrolytes, and blood gases, and to test for infection; **lumbar puncture** (spinal tap) to test for central nervous system infection; x ray, **computed tomography scans** (CT), or **magnetic resonance imaging** (MRI) scans to look for tumors, hemorrhage, or other brain abnormality; thyroid tests; **electroencephalography** (EEG); **electrocardiography** (ECG); and possibly others as dictated by the likely cause.

Treatment

Treatment of delirium begins with recognizing and treating the underlying cause. Delirium itself is managed by reducing disturbing stimuli, or providing soothing ones; use of simple, clear language in communication; and reassurance, especially from family members. Physical restraints may be needed if the patient is a danger to himself or others, or if he insists on removing necessary medical equipment such as intravenous lines or monitors. Sedatives or **antipsychotic drugs** may be used to reduce **anxiety**, hallucinations, and delusions.

Prognosis

Persons with delirium usually have a worse prognosis for the underlying disease than persons without delirium. Nonetheless, those without terminal illness usually recover from delirium. They may not regain all their original cognitive abilities, and may be left with some permanent impairments, including **fatigue**, irritability, difficulty concentrating, or mood changes.

Prevention

Prevention of delirium is focused on treating or avoiding its underlying causes. The most preventable forms are those induced by drugs. Strategies for reducing delirium include following prescriptions, consulting the prescribing physician immediately if symptoms occur, and consulting the physician before discontinuing the drug, even if it has been ineffective; avoiding intoxication with legal or illegal drugs, and seeking professional assistance before suddenly discontinuing an addictive drug such as alcohol or heroin. Maintaining good **nutrition**, which promotes general health, can minimize the likelihood of delirium from alcohol intoxication and withdrawal. Avoidance of exposure to solvents, insecticides, heavy metals, or biological poisons in the home or workplace is also important.

Delusions

Definition

A delusion is an unshakable belief in something untrue. These irrational beliefs defy normal reasoning, and remain firm even when overwhelming proof is presented to dispute them. Delusions are often accompanied by **hallucinations** and/or feelings of **paranoia**, which act to strengthen confidence in the delusion. They are distinct from culturally or religiously based beliefs that may be seen as untrue by outsiders.

Description

Delusions are a common symptom of several mood and personality-related mental illnesses, including **schizoaffective disorder**, **schizophrenia**, shared psychotic disorder, major depressive disorder, and **bipolar disorder**. They are also the major feature of delusional disorder. Individuals with delusional disorder have long-term, complex delusions that fall into one of six categories: persecutory, grandiose, jealousy, erotomanic, somatic, or mixed. There are also delusional disorders such as **dementia** that clearly have organic or physical causes.

Persecutory

Individuals with persecutory delusional disorder are plagued by feelings of paranoia and an irrational, unshakable belief that someone is plotting against them, or out to harm them.

Grandiose

Individuals with grandiose delusional disorder have an inflated sense of self-worth. Their delusions center on their own importance, such as believing that they have done or created something of extreme value or have a "special mission."

Jealousy

Jealous delusions are unjustified and irrational beliefs that an individual's spouse or significant other has been unfaithful.

Erotomanic

Individuals with erotomanic delusional disorder believe that another person, often a stranger, is in love with them. The object of their affection is typically of a higher social status, sometimes a celebrity. This type of delusional disorder may lead to stalking or other potentially dangerous behavior.

Somatic

Somatic delusions involve the belief that something is physically wrong with the individual. The delusion may involve a medical condition or illness or a perceived deformity. This condition differs from **hypochondriasis** in that the deformity is perceived as a fixed condition not a temporary illness.

Mixed

Mixed delusions are characterized by two or more of persecutory, grandiose, jealousy, erotomanic, or somatic themes.

Causes and symptoms

Some studies have indicated that delusions may be generated by abnormalities in the limbic system, the portion of the brain on the inner edge of the cerebral cortex that is believed to regulate emotions. The exact source of delusions has not been conclusively found, but potential causes include genetics, neurological abnormalities, and changes in brain chemistry. Delusions are a known possible side effect of drug use and abuse (e.g., amphetamines, cocaine, PCP).

Diagnosis

Patients with delusional symptoms should undergo a thorough **physical examination** and patient history to rule out possible organic causes (such as dementia). If a psychological cause is suspected, a mental health professional will typically conduct an interview with the patient and administer one of several clinical inventories, or tests, to evaluate mental status.

Treatment

Delusions that are symptomatic of delusional disorder should be treated by a psychologist and/or psychiatrist. Though **antipsychotic drugs** are often not

WWW.BOOKBAZ.IR

KEY TERMS

Hallucinations—False or distorted sensory experiences that appear to be real perceptions.

Paranoia—An unfounded or exaggerated distrust of others.

Shared psychotic disorder—Also known as folie à deux; shared psychotic disorder is an uncommon disorder in which the same delusion is shared by two or more individuals.

effective, antipsychotic medication such as thioridazine (Mellaril), haloperidol (Haldol), chlorpromazine (Thorazine), clozapine (Clozaril), or risperidone (Risperdal) may be prescribed, and cognitive therapy or **psychotherapy** may be attempted.

If an underlying condition such as schizophrenia, depression, or drug abuse is found to be triggering the delusions, an appropriate course of medication and/or psychosocial therapy is employed to treat the primary disorder. The medication typically includes an antipsychotic agent.

Prognosis

Delusional disorder is typically a chronic condition, but with appropriate treatment, a remission of delusional symptoms occurs in up to 50% of patients. However, because of their strong belief in the reality of their delusions and a lack of insight into their condition, individuals with this disorder may never seek treatment, or may be resistant to exploring their condition in psychotherapy.

REVISED BY LAURA JEAN CATALDO, RN, EDD

Dementia

Definition

The American Pyschiatric Association renamed **dementia** as **major neurocognitive disorder** in the *Diagnostic and Statistical Manual of Mental Disorders* (DSM-5) in order to reduce the stigma associated with the word dementia. Dementia/major neurocognitive disorder is a condition characterized by a progressive, irreversible decline in mental ability, accompanied by changes in behavior, personality, and in the late stage, motor functions.

In major neurocognitive disorder, there is a measurable loss in more than one of the following domains: memory, attention, learning, language, perception, and social interaction. These losses must be severe enough to impair the ability of a person to perform a function such as paying bills or managing medication or to interact socially. Similar declines that do not impair daily functioning are classified as mild neurocognitive disorders. This operating definition encompasses 70–80 different types of major neurocognitive disorder. They include changes due to diseases (e.g., Alzheimer disease and Creutzfeldt-Jakob disease), changes due to **stroke** or repeated blows to the head (as suffered by boxers or football players), and damage due to long-term alcohol abuse.

Demographics

The prevalence of major neurocognitive disorder increases rapidly with age. It affects about 1% of

people age 60–64 and approximately doubles every five years after age 60. By age 85, major neurocognitive disorder affects between 30% and 50% of the population in the United States, with the absolute number of individuals increasing as the population ages. The condition is somewhat more common among women than men. Some studies suggest that the risk for major neurocognitive disorder is higher among African Americans and Hispanic Americans than it is for Caucasians. More than half of all nursing home admissions occur because of major neurocognitive disorder. Surveys have found that major neurocognitive disorder is the condition most feared by older adults in the United States.

The demographic distribution of major neurocognitive disorder varies according to the cause. Moreover, recent research indicates that major neurocognitive disorder in many individuals has overlapping causes, so that it is not always easy to assess the true rates of occurrence of the different types. For example, Alzheimer disease (AD) and multi-infarct dementia (MID) are found together in about 15–20% of cases.

Alzheimer disease

AD is by far the most common cause of major neurocognitive disorder in the elderly, accounting for 60–80% of cases. It is estimated that about 5 million adults in the United States have AD. The disease strikes women more often than men, but researchers do not know yet whether the sex ratio simply reflects the fact that women tend to live longer than men or whether female sex is itself a risk factor for AD.

Multi-infarct dementia

MID is responsible for between 15% and 20% of cases of major neurocognitive disorder (not counting cases in which it coexists with AD). Unlike AD, MID is more common in men than in women. Diabetes, high blood pressure, a history of **smoking**, and **heart disease** are all risk factors for MID. Researchers have suggested that MID is underdiagnosed, and may coexist with other major neurocognitive disorders more frequently than is presently recognized.

Major neurocognitive disorder with Lewy bodies

Major neurocognitive disorder with Lewy bodies is now thought to be the second most common form of major neurocognitive disorder after Alzheimer disease, but because researchers do not completely understand the relationship between Lewy bodies, AD, and Parkinson's disease, the demographic distribution of this type of major neurocognitive disorder is also unclear.

Other major neurocognitive disorders

Frontotemperal lobe degeneration (FLD), Pick disease, Huntington disease, Parkinson's disease, HIV infection, prion diseases, **alcoholism**, **traumatic brain injury**, and other causes of major neurocognitive disorder account for about 10% of all cases. In FLD and Pick disease, women appear to be affected slightly more often than men.

Description

The definition of major neurocognitive disorder has become more inclusive over the past several decades. Whereas earlier descriptions of major neurocognitive disorder emphasized **memory loss**, the current *DSM-5* of the American Psychiatric Association defines major neurocognitive disorder as an overall decline in intellectual function, including difficulties with language, simple calculations, planning and judgment, social interactions, and abstract reasoning, as well as loss of memory. Major neurocognitive disorder is not caused simply by **aging**, although it is quite common in older people. Many researchers regard it as resulting from injuries, infections, brain diseases, tumors, biochemical changes within the brain, or other disorders.

One of the challenges for health care professionals is to differentiate the early-stage cognitive deficits of major neurocognitive disorder from normal age-related memory impairment. Individuals with age-related memory impairment may tend to learn new information more slowly, but given additional time, their cognitive performance usually is adequate. Other problems that may be mistakenly labeled major neurocognitive disorder include **delirium**, **psychosis**, depression, and the side effects of various medications

Major neurocognitive disorder can be caused by as many as eighty different diseases and conditions, ranging from dietary deficiencies and metabolic disorders to head injuries and inherited diseases. The possible causes of major neurocognitive disorder can be categorized as follows:

- Primary major neurocognitive disorder. These major neurocognitive disorders are characterized by damage to or wasting away of the brain tissue itself. They include Alzheimer disease (AD), Pick disease, and FLD.
- Multi-infarct dementia (MID). Sometimes called vascular major neurocognitive disorder, this type is

WWW.BOOKBAZ.IR

caused by blood clots in the small blood vessels of the brain. When the clots cut off the blood supply to the brain tissue, the brain cells are damaged and may die.

- Lewy body major neurocognitive disorder. Lewy bodies are areas of injury found on damaged nerve cells in certain parts of the brain. They are associated with AD and Parkinson's disease, but researchers do not yet know whether major neurocognitive disorder with Lewy bodies is a distinct type of major neurocognitive disorder or a variation of AD or Parkinson's disease.
- Major neurocognitive disorders related to alcoholism or exposure to heavy metals (e.g., arsenic, antimony, bismuth, mercury).
- Major neurocognitive disorder related to infectious diseases. These infections may be caused by viruses (e.g., HIV, viral encephalitis); spirochetes (e.g., Lyme disease, syphilis); or prions (e.g., Creutzfeldt-Jakob disease).
- Major neurocognitive disorder related to abnormalities in the structure of the brain. These may include a buildup of spinal fluid in the brain (hydrocephalus), tumors, or blood collecting beneath the membrane that covers the brain (subdural hematoma).

Major neurocognitive disorder may also be associated with depression, low levels of thyroid hormone, niacin, or vitamin (B_{12}) deficiency. Major neurocognitive disorder related to these conditions is often reversible.

Risk factors

Genetic factors play a role in several types of major neurocognitive disorder, but the importance of these factors in the development of the major neurocognitive disorder varies considerably. Alzheimer disease (AD) is known, for example, to have an autosomal (non-sex-related) dominant pattern in most early-onset cases as well as in some late-onset cases, and to show different degrees of penetrance (frequency of expression) in late-life cases. Researchers have not yet discovered how the genes associated with major neurocognitive disorder interact with other risk factors to produce or trigger the major neurocognitive disorder. One non-genetic risk factor presently being investigated is toxic substances in the environment.

Causes and symptoms

There are many different causes of major neurocognitive disorder. What they all have in common is damage to or degeneration of nerve cells in the brain.

Major neurocognitive disorder is marked by a gradual impoverishment of thought and other mental activities. Losses eventually affect virtually every aspect of mental functioning. The slow progression of major neurocognitive disorder is in contrast with delirium, which involves some of the same symptoms, but has a very rapid onset and fluctuating course with alteration in the level of consciousness. However, delirium may occur with major neurocognitive disorder, especially since the person with major neurocognitive disorder is more susceptible to the delirium-inducing effects of many types of drugs.

Early-onset Alzheimer disease

In early-onset AD, which accounts for 2–7% of cases of AD, the symptoms develop before age 60. Early-onset AD usually is caused by an inherited genetic mutation. Early-onset AD is also associated with **Down syndrome**, in that persons with trisomy 21 (three forms of human chromosome 21 instead of a pair) often develop early-onset AD.

Late-onset Alzheimer disease

Research indicates that late-onset Alzheimer disease is a polygenic disorder; that is, its development is influenced by more than one gene. It has been known since 1993 that a specific form of a gene for apolipoprotein E (APOE) on human chromosome 19 is a genetic risk factor for late-onset AD. In 1998, researchers at the University of Pittsburgh reported on another gene that controls the production of bleomycin hydrolase (BH) as a second genetic risk factor that acts independently of the APOE gene. In December 2000, three separate research studies reported that a gene on chromosome 10 that may affect the processing of amyloid-beta protein is also involved in the development of late-onset AD. Research in the genetic factors affecting AD is ongoing.

Multi-infarct dementia (MID)

While the chief risk factors for MID are high blood pressure, advanced age, and male sex, there is an inherited form of MID called CADASIL, which stands for cerebral autosomal dominant arteriopathy with subcortical infarcts and leukoencephalopathy. CADASIL can cause psychiatric disturbances and severe headaches as well as major neurocognitive disorder.

Several studies have documented a link between elevated levels of an amino acid called **homocysteine** in the blood and the risk of developing major neurocognitive disorder, likely vascular major neurocognitive

disorder. As homocysteine concentration can be modified by diet, the finding holds the potential that one risk factor for major neurocognitive disorder may be controllable.

Frontal lobe major neurocognitive disorders

Researchers think that between 25% and 50% of cases of frontotemporal lobe degeneration involve genetic factors. Pick disease appears to have a much smaller genetic component than FLD. It is not yet known what other risk factors combine with inherited traits to influence the development of frontal lobe major neurocognitive disorders.

Familial British dementia (FBD)

FBD is a rare autosomal dominant disorder that was first reported in the 1940s in a large British family extending over nine generations. FBD resembles Alzheimer in that the individual develops a progressive major neurocognitive disorder related to amyloid deposits in the brain. In 1999, a mutated gene that produces the amyloid responsible for FBD was discovered on human chromosome 13. Studies of this mutation may yield further clues to the development of Alzheimer disease as well as FBD itself.

Creutzfeldt-Jakob disease

Although Creutzfeldt-Jakob disease is caused by a prion, researchers think that 5–15% of cases may have a genetic component.

Symptoms

The *DSM-5* distinguishes major neurocognitive disorder from mild neurocognitive disorder and specifies criteria that must be met for an individual to be diagnosed with major neurocognitive disorder. In addition the *DSM-5* emphasizes identifying the cause of the neurocognitive deficit and documenting the deficit with observations of others close to the individual and through performance on standardized neurophysical testing. The cognitive deficit must occur in at least two areas: memory, attention, learning, language, perception, and social interaction. In addition, The individual must be found to have two or more of the following deficits:

- Memory. Difficulty learning new information as well as recalling previously learned information.
- Aphasia. Aphasia refers to loss of language function. People with major neurocognitive disorder may use vague words like "it" or "thing" because they cannot recall the exact name of an object. They also may echo what other people say, or repeat a word or phrase over and over. People in the later stages of major neurocognitive disorder may totally stop speaking.
- Apraxia. Apraxia refers to loss of the ability to perform intentional movements even though the person is not paralyzed, has not lost their sense of touch, and knows what they are trying to do. For example, an individual with apraxia may stop brushing their teeth, or have trouble tying their shoelaces.
- Agnosia. Agnosia refers to loss of the ability to recognize objects even though the person's sight and sense of touch are normal. People with severe agnosia may fail to recognize family members or their own face reflected in a mirror.
- Problems with abstract thinking and complex behavior. This criterion refers to the loss of the ability to make plans, carry out the steps of a task in the proper order, make appropriate decisions, evaluate situations, show good judgment, etc. For example, a person with major neurocognitive disorder might light a stove burner under a saucepan before putting food or water in the pan or be unable to record checks and balance his or her checkbook.

The *DSM-5* also specifies that these deficits must be severe enough to cause serious problems in the person's daily life, and these disturbances they must represent a decline from a previously higher level of functioning.

Signs and symptoms presented by the patient are used to differentiate among the various types of major neurocognitive disorder during a diagnostic evaluation.

ALZHEIMER DISEASE. Major neurocognitive disorder related to AD often progresses slowly; it may be accompanied by irritability, wide mood swings, and personality changes in the early stage. In second-stage AD, the individual typically gets lost easily, is completely disoriented with regard to time and space, and may become angry, uncooperative, or aggressive. In final-stage AD, the individual is completely bedridden, has lost control over bowel and bladder functions, and may be unable to swallow or eat. The risk of seizures increases as the individual progresses from early to end-stage AD. Death usually results from an infection or **malnutrition**.

Multi-infarct dementia

In MID, symptoms are more likely to occur after age 70. In the early stages, the individual retains his or her personality more fully than an individual with AD. Another distinctive feature of this type of major neurocognitive disorder is that it often progresses in a

WWW.BOOKBAZ.IR

KEY TERMS

Agnosia—Loss of the ability to recognize objects by use of the physical senses.

Amyloid—A waxy translucent substance composed mostly of protein, that forms plaques (abnormal deposits) in the brain.

Aphasia—Loss of previously acquired ability to speak, or to understand written or spoken language.

Apraxia—Impairment of the ability to make purposeful movements, but not paralysis or loss of sensation.

Creutzfeldt-Jakob disease—A degenerative disease of the central nervous system caused by a prion, or "slow virus."

Delirium—A disturbance of consciousness marked by confusion, difficulty paying attention, delusions, hallucinations, or restlessness. It can be distinguished from major neurocognitive disorder by its relatively sudden onset and variation in the severity of the symptoms.

Hematoma—An accumulation of blood, often clotted, in a body tissue or organ, usually caused by a break or tear in a blood vessel.

Huntington disease—A midlife-onset inherited disorder characterized by progressive major neurocognitive disorder and loss of control over voluntary movements. It is sometimes called Huntington's chorea.

Hydrocephalus—The excess accumulation of cerebrospinal fluid around the brain, often causing enlargement of the head.

Lewy bodies—Areas of injury found on damaged nerve cells in certain parts of the brain associated with major neurocognitive disorder.

Multi-infarct dementia—Major neurocognitive disorder caused by damage to brain tissue resulting from a series of blood clots or clogs in the blood vessels. It is also called vascular major neurocognitive disorder.

Parkinson's disease—A disease of the nervous system most common in people over 60, characterized by a shuffling gait, trembling of the fingers and hands, and muscle stiffness. It may be related in some way to Lewy body major neurocognitive disorder.

Pick's disease—A rare type of primary major neurocognitive disorder that affects the frontal lobes of the brain. It is characterized by a progressive loss of social skills, language, and memory, leading to personality changes and sometimes loss of moral judgment.

stepwise fashion; that is, the individual shows rapid changes in functioning, then remains at a plateau for a while rather than showing a continuous decline. The symptoms of MID may also have a "patchy" quality; that is, some of the individual's mental functions may be severely affected while others are relatively undamaged. Other symptoms of MID include exaggerated reflexes, an abnormal gait (manner of walking), loss of bladder or bowel control, and inappropriate laughing or crying.

Major neurocognitive disorder with Lewy bodies

This type of major neurocognitive disorder may combine some features of AD, such as severe memory loss and confusion, with certain symptoms associated with Parkinson's disease including stiff muscles, a shuffling gait, and trembling or shaking of the hands. Visual **hallucinations** may be one of the first symptoms of major neurocognitive disorder with Lewy bodies.

Frontotemporal lobe disorders

The frontotemporal lobe major disorders are gradual in onset. Pick major neurocognitive disorder is most likely to develop in persons between ages 40 and 60, while FLD typically begins before age 65. The first symptoms of the FLD often include socially inappropriate behavior (e.g., rude remarks, sexual acting-out, lack of personal hygiene). Individuals often are obsessed with eating and may put non-food items in their mouths as well as making frequent sucking or smacking noises. In the later stages of frontal lobe major neurocognitive disorder or Pick's disease, the individual may develop muscle weakness, twitching, and **delusions** or hallucinations.

Creutzfeldt-Jakob disease

The major neurocognitive disorder associated with Creutzfeldt-Jakob disease occurs most often in persons between ages 40 and 60. It is typically preceded by a period of several weeks in which the individual complains of unusual tiredness, **anxiety**, loss of appetite, or difficulty concentrating. This type of major neurocognitive disorder also usually progresses much more rapidly than other major neurocognitive disorders, usually over a span of a few months.

In some cases, a patient's primary physician may be able to diagnose the major neurocognitive disorder; in many instances, however, the patient will be referred to a neurologist, psychiatrist, or a specialist in geriatric medicine. The differential diagnosis of major neurocognitive disorder is complicated because of the number of possible causes, because more than one cause may be present, and because major neurocognitive disorder can coexist with other conditions such as depression and delirium. Delirium is a temporary disturbance of consciousness marked by confusion, restlessness, inability to focus one's attention, hallucinations, or delusions. In elderly people, delirium is frequently a side effect of surgery, medications, infectious illnesses, or **dehydration**. Delirium can be distinguished from major neurocognitive disorder by the fact that delirium usually comes on suddenly (in a few hours or days) and may vary in severity—it is often worse at night. Major neurocognitive disorder develops much more slowly, over a period of months or years, and the patient's symptoms are relatively stable. It is possible for a person to have delirium and major neurocognitive disorder at the same time.

Another significant diagnostic distinction in elderly patients is the distinction between major neurocognitive disorder and age-associated memory impairment (AAMI). Older people with AAMI have a mild degree of memory loss; they do not learn new information as quickly as younger people, and they may take longer to recall a certain fact or to balance their checkbook, but they do not have the degree of memory impairment that characterizes major neurocognitive disorder, and they do not get progressively worse.

Patient history

The doctor will begin by taking a full history, including the patient's occupation and educational level as well as medical history. The occupational and educational history allows the examiner to make a more accurate assessment of the extent of the patient's memory loss and other evidence of intellectual decline. In some cases, the occupational history may indicate exposure to heavy metals or other toxins. A complete medical history allows the doctor to assess possibilities such as delirium, depression, alcohol-related major neurocognitive disorder, major neurocognitive disorder related to **head injury**, or major neurocognitive disorder caused by infection. It is particularly important for the doctor to have a list of all the patient's medications, including over-the-counter preparations, because of the possibility that the patient's symptoms are related to side effects.

Mental status examination

A mental status examination (MSE) evaluates the patient's ability to communicate, follow instructions, recall information, perform simple tasks involving movement and coordination, as well as his or her emotional state and general sense of space and time. The MSE includes the doctor's informal evaluation of the patient's appearance, vocal tone, facial expressions, posture, and gait as well as formal questions or instructions. A common form that has been used since 1975 is the so-called Folstein Mini-Mental Status Examination, or MMSE. Questions that are relevant to diagnosing major neurocognitive disorder include asking the patient to count backward from 100 by 7s, to make change, to name the current President, to repeat a short phrase after the examiner (e.g., "no ifs, ands, or buts") to draw a clock face or geometric figure, and to follow a set of instructions involving movement (e.g., "Show me how to throw a ball" or "Fold this piece of paper and place it under the lamp on the bookshelf"). The examiner may test the patient's abstract reasoning ability by asking him or her to explain a familiar proverb (e.g. "People who live in glass houses shouldn't throw stones") or test the patient's judgment by asking about a problem with a common-sense solution, such as what one does when a prescription runs out.

Neurological examination

A neurological examination includes an evaluation of the patient's cranial nerves and reflexes. The cranial nerves govern the ability to speak as well as sight, hearing, taste, and smell. The patient will be asked to stick out the tongue, follow the examiner's finger with the eyes, raise the eyebrows, etc. The patient is also asked to perform certain actions (e.g., touching the nose with the eyes closed) that test coordination and spatial orientation. The doctor will usually touch or tap certain areas of the body, such as the knee or the sole of the foot, to test the patient's reflexes. Failure to respond to the touch or tap may indicate damage to certain parts of the brain.

Tests

LABORATORY TESTS. Blood and urine samples are collected in order to rule out such conditions as thyroid deficiency, niacin (vitamin B_{12}) deficiency, **heavy metal poisoning**, **liver disease**, HIV infection, **syphilis**, anemia, medication reactions, or kidney failure. A **lumbar puncture** (spinal tap) may be done to rule out neurosyphilis.

WWW.BOOKBAZ.IR

DIAGNOSTIC IMAGING. The patient may be given a CT (computed tomography) scan or MRI (**magnetic resonance imaging**) to detect evidence of strokes, disintegration of the brain tissue in certain areas, **blood clots** or tumors, a buildup of spinal fluid, or bleeding into the brain tissue. PET (positron-emission tomography) or SPECT (single-emission computed tomography) imaging is not used routinely to diagnose major neurocognitive disorder, but may be used to rule out Alzheimer disease or frontal lobe degeneration if a patient's CT scan or MRI is unrevealing.

Treatment

Reversible and responsive major neurocognitive disorders

Some types of major neurocognitive disorder are reversible, and a few types respond to specific treatments related to their causes. Major neurocognitive disorder related to dietary deficiencies or metabolic disorders is treated with the appropriate **vitamins** or thyroid medication. Major neurocognitive disorder related to HIV infection often responds well to zidovudine (Retrovir), a drug given to prevent the **AIDS** virus from replicating. Multi-infarct dementia is usually treated by controlling the patient's blood pressure and/or diabetes; while treatments for these disorders cannot undo damage already caused to brain tissue, they can slow the progress of the major neurocognitive disorder. Patients with alcohol-related major neurocognitive disorder often improve over the long term if they are able to stop drinking. Major neurocognitive disorders related to head injuries, **hydrocephalus**, and tumors are treated by surgery.

It is important to evaluate and treat elderly patients for depression, because the symptoms of depression in older people often mimic major neurocognitive disorder. In addition, patients who suffer from both depression and major neurocognitive disorder often show some improvement in intellectual functioning when the depression is treated.

Irreversible major neurocognitive disorders

There are no medications or surgical techniques that can cure Alzheimer disease, the frontal lobe major neurocognitive disorders, MID, or major neurocognitive disorder with Lewy bodies. There are also no "magic bullets" that can reverse or stop the progression of these major neurocognitive disorders.

Early intervention may allow the patient to compensate for the alterations in functioning, help to minimize complications, and have an improved quality of life. It may also allow the patient and family to plan for the future and to identify resources.

Drugs

Periodically, new drugs are studied for the treatment of major neurocognitive disorder. The only drugs approved as of 2014 for the symptomatic treatment of AD were tacrine (Cognex), donepazil (Aricept), rivastigmine (Exelon) and galantamine (Reminyl). These drugs may provide temporary improvement in cognitive functioning for about 40% of patients with mild-to-moderate AD. However, drug therapy can be complicated by forgetfulness, especially if the drug must be taken several times a day.

Psychotic symptoms, including **paranoia**, delusions, and hallucinations, may be treated with **antipsychotic drugs** such as haloperidol, chlorpromazine, risperidone, and clozapine. Side effects of these drugs can be significant. Anti-anxiety drugs such as diazepam (Valium) may improve behavioral symptoms, especially agitation and anxiety although buspirone (BuSpar) has fewer side effects. The anticonvulsant carbamazepine (Tegretol) is also sometimes prescribed for agitation. Depression is treated with antidepressants, usually beginning with **selective serotonin reuptake inhibitors** (SSRIs) such as fluoxetine (Prozac) or paroxetine (Paxil).

In general, medications are administered cautiously in the lowest possible effective doses to individuals with major neurocognitive disorder in order to minimize side effects. Supervision of taking medications is generally required.

The primary goals of treatment for progressive major neurocognitive disorders are to preserve as much functioning and independence as possible and to maintain quality of life as long as possible. Caring for a person with major neurocognitive disorder can be difficult and complex. The patient must cope with functional and cognitive limitations, while family members or other caregivers must assume increasing responsibility for the person's physical needs. The patient and family should be educated early on in the disease progression to help them anticipate and plan for inevitable changes.

Behavioral treatment

Behavioral approaches may be used to reduce the frequency or severity of problem behaviors such as aggression or socially inappropriate conduct. Problem behavior may be a reaction to frustration or overstimulation. Understanding and modifying the situations that trigger it can be effective; strategies may

include breaking down complex tasks such as dressing or feeding into simpler steps, or reducing the amount of activity in the environment to avoid confusion and agitation. Pleasurable activities such as crafts, games, and music can provide therapeutic stimulation and improve mood.

Home modification

Modifying the environment can increase safety and comfort while decreasing agitation. Home modifications for safety include removal or lock-up of hazards such as sharp knives, dangerous chemicals, and tools. Childproof latches may be used to limit access as well. Bed rails and bathroom safety rails can be important safety measures. Confusion may be reduced with the use of simpler decorative schemes and the presence of familiar objects. Covering or disguising doors may reduce the tendency to wander. Positioning the bed in view of the bathroom can decrease incontinence.

Long-term institutional care may be required for the person with major neurocognitive disorder, as profound cognitive losses often precede death by a number of years. Early planning for the financial burden of nursing **home care** is critical. Useful information about financial planning for long-term care is available through the Alzheimer's Association.

Family members or others caring for a person with major neurocognitive disorder are often subject to extreme **stress**, and may develop feelings of anger, resentment, guilt, and hopelessness, in addition to the sorrow they feel for their loved one and for themselves. Depression is an extremely common consequence of being a full-time caregiver for a person with major neurocognitive disorder. Support groups can be an important way to deal with the stress of care giving. Contact numbers are available from the Alzheimer's Association; they may also be available through a local social service agency.

Alternatives

No alternative therapies have been found to conclusively prevent, reverse, or slow major neurocognitive disorders except for those caused by nutrient deficiencies. However, alternative practitioners find some of the following helpful to individual patients.

NUTRITIONAL SUPPLEMENTS. Some **nutritional supplements** may be helpful, especially if major neurocognitive disorder is caused by deficiency of these essential nutrients:

- Acetyl-L-carnitine may improve brain function and increases attention span, enhances ability to concentrate and increases energy in individuals with Alzheimer's disease.
- Antioxidants (vitamin E, vitamin C, beta-carotene, or selenium): may reduce the risk of contracting major neurocognitive disorder by reducing the damaging effects of free radicals.
- B-complex vitamins and vitamin B_{12} may significantly improve mental function in individuals who have low levels of these essential nutrients.
- Coenzyme Q10 may help deliver more oxygen to the brain.
- DHEA may increase brain function in the elderly.
- Magnesium may be helpful if the major neurocognitive disorder is caused by magnesium deficiency and/or accumulation of aluminum in the brain.
- Phosphotidylserine deficiency may decrease mental function and cause depression.
- Zinc may boost short-term memory and increase attention span.

Herbal treatment

Herbal remedies that may be helpful in treating major neurocognitive disorder include Chinese or Korean **ginseng**, Siberian ginseng, gotu kola, and *Ginkgo biloba*. Of these, **ginkgo biloba** is the most well known and widely accepted by Western medicine, but has yet been proved to have a definitive positive effect on memory.

Homeopathy

A homeopathic physician may prescribe patient-specific homeopathic remedies to alleviate symptoms of major neurocognitive disorder.

Acupressure

This form of therapy uses hands to apply pressure on specific **acupressure** points to improve blood circulation and calm the nervous system.

Aromatherapy

Aromatherapists use essential oils as inhalants or in baths to improve mental performances and to calm the nerves.

Prognosis

The prognosis for reversible major neurocognitive disorder related to nutritional or thyroid problems are usually good once the cause has been identified and treated. The prognoses for major neurocognitive disorders related to alcoholism or HIV infection depend

WWW.BOOKBAZ.IR

on the patient's age and the severity of the underlying disorder.

For those with irreversible progressive major neurocognitive disorder, the outlook often includes slow deterioration in mental and physical capacities ending in death. Eventually, help is often required when swallowing, walking, and even sitting become difficult. Aid can consist of preparing special **diets** that can be more easily consumed and making surroundings safe in case of falls. Lift assists in areas such as the bathroom can also be useful. On average, people with Alzheimer disease live eight years past their diagnosis, with a range from one to 20 years. Patients with frontal lobe major neurocognitive disorder or Pick disease live on average between 5 and 10 years after diagnosis. The course of Creutzfeldt-Jakob disease is much more rapid, with patients living between 5 and 12 months after diagnosis. Vascular major neurocognitive disorder is usually progressive, with death resulting from stroke, infection, or heart disease.

Prevention

Major neurocognitive disorder caused by repeated blows to the head can be prevented by avoiding sports where head **trauma** is common. Alcohol-abuse related major neurocognitive disorder can be prevented by avoiding alcohol or minimized by receiving early treatment for alcoholism. Good **nutrition** can prevent nutrient-deficiency major neurocognitive disorder. Unfortunately, most forms of major neurocognitive disorder cannot be prevented.

Dengue fever

Definition

Dengue **fever**, also known as break bone fever, is a disease caused by several closely related viruses (called serotypes) of the genus *Flavivirus*. These viruses, which are known as DEN-1, DEN-2, DEN-3, and DEN-4, are collectively termed "dengue virus" or "dengue arbovirus." An arbovirus is a virus carried by an insect or other arthropod. Female mosquitoes transmit the dengue virus to humans. Although the disease is rare within the continental United States, dengue fever is common in many areas of the world, especially tropical and subtropical regions.

Description

Unlike the **common cold** or **influenza**, the dengue virus is not passed directly from person to person. Rather, the virus requires another entity, known as an intermediate vector, to carry it from one infected individual to another. The intermediate vectors for dengue fever are mosquitos, and the specific mosquitos that carry the viruses responsible for dengue fever are in the genus *Aedes*. One species, *A. aegypti*, is the principal intermediate vector for dengue virus, and is also responsible for transmitting other diseases, including **yellow fever**. It is the female mosquito that

transmits the virus, because the female requires protein attained via blood meals for the development of her eggs.

Most people recover from dengue fever without lasting health issues, but in some patients, the disease progresses into more dangerous conditions called dengue hemorrhagic fever or dengue **shock** syndrome, which can cause death.

Origins

A Chinese medical encyclopedia in 992 first recorded a disease that appears to be dengue fever. It got the name dengue fever in 1779, possibly a corruption of the Swahili phrase "ka dinga pepo" that was used to describe one of the symptoms—cramp-like seizure—associated with the disease. Beginning in the mid-1700s, the disease spread to many regions of the world via the growing shipping industry, and the first epidemics of dengue fever were noted in the 1780s in port areas of Asia, Africa, and North America. This included a 1780 outbreak in Philadelphia, during which Dr. Benjamin Rush, one of the signers of the Declaration of Independence dubbed it "break bone fever" in reference to the terrific joint **pain** it caused.

Since then, dengue fever has dispersed to much of the world, although it is still more prevalent in tropical and subtropical regions. Today, about two of every five people living on Earth reside in the areas where there is a risk of dengue fever. According to the World Health Organization (WHO), 50–100 million people are infected with dengue virus every year. Comparing the number of cases of dengue fever reported to the organization, the WHO noted 908 during the period 1955–1959, but 968,564 in the period 2000–2007. Although WHO-reported numbers represent just a fraction of actual cases, its tally provides an idea of magnitude of spread of Dengue fever in the past several decades.

Dengue fever remains rare in the continental United States, typically only occurring in people who have traveled to tropical or subtropical regions, but outbreaks do happen. For instance, an outbreak occurred in south Texas in 2005. In addition, there have been epidemics in Puerto Rico, Samoa, Guam, and the U.S. Virgin Islands.

Causes and symptoms

Causes

When a mosquito bites a person who has dengue fever, it can pick up the virus from the person's blood. This typically occurs at the point in a person's disease cycle when the level of virus in the blood is very high. The virus then multiplies in the mosquito's body for about 8–12 days. By then, there is enough virus in the mosquito's body, including its saliva, for it to transmit the virus to another person through its bite. The infected mosquito may infect multiple people during its approximately month-long lifespan.

After a person has been infected with the dengue virus, the arbovirus begins multiplying, and in about four days, a high level of the virus is circulating in the patient's body. The patient will continue to have a high level of virus for anywhere from five to 12 days, so plenty of time elapses for numerous mosquitoes to potentially bite the patient and become intermediate vectors to spread the virus to other people.

Symptoms

Some patients have a mild case of dengue fever and show no or very limited symptoms. Among those who do show symptoms, symptoms begin to occur about five days after following infection via the mosquito's bite, although the advent of symptoms may begin anywhere from day four to day 10. Symptoms include:

- high fever, possibly up to 106°F (41°C)
- extreme headaches
- severe pain behind the eyes
- excruciating joint pain
- muscle pain
- bone pain
- widespread rash
- nausea and/or vomiting
- minor bleeding of the nose or gums
- low white blood cell (WBC) count

Usually, the patient recovers within a week or so of the advent of symptoms. Sometimes, however, symptoms continue and extend due to damage incurred by blood vessels and to a decrease in platelets (clot-forming cells in the blood). When this occurs, patients should seek immediate medical assistance. These symptoms include:

- bleeding from the nose or mouth
- vomiting that continues
- easy bruising or petechiae (small reddish or purplish spots on the skin caused by broken capillaries)
- severe abdominal pain

In rare cases, patients may develop a more serious form of the condition called dengue hemorrhagic fever (DHF), which is life threatening. DHF is most common among individuals who have had a bout with dengue fever previously. The symptoms of DHF

WWW.BOOKBAZ.IR

appear 3–7 days after the original, classical symptoms. They include a persistent and intense abdominal pain; continued **vomiting**, often accompanied by blood; bleeding gums; exhaustion; and rapid breathing. Patients with DHF may also experience dengue shock syndrome, which is a sudden and substantial drop in blood pressure, often accompanied by a weak and rapid pulse, cold and clammy skin, **dry mouth**, and diminished urine flow. DNF and dengue shock syndrome require immediate medical treatment. Without treatment, the patient may die.

Diagnosis

Healthcare professionals take into account the geographic location of the patient, since dengue fever is more prevalent in certain regions of the world. Patients who are just returning from a trip to an at-risk region should inform their doctor of their travels. A telltale symptom is the presence of a high fever that continues for two to seven days, especially if accompanied by two or more of the classical symptoms noted above. Often, however, dengue fever is difficult to positively identify because the symptoms are similar to those manifesting in other illnesses, such as **malaria** or **typhoid fever**. To diagnose DHF or dengue shock syndrome, the healthcare professional will consider the timing, type and severity of symptoms, as well as any previous bouts with dengue fever.

To verify a diagnosis of dengue fever, a medical professional may order a blood test to detect evidence of the virus. Usually, however, the fever will have run its course by the time the results come back. A diagnosis can, however, be helpful information if the illness progresses to DHF or dengue shock syndrome.

Treatment

No cure is available for dengue fever, and no treatment is available to shorten the course of dengue fever, DHF, or dengue shock syndrome. Healthcare professionals recommend bed rest and plenty of fluids to prevent **dehydration**. They may prescribe or recommend medications to lower the fever and to decrease the pain of muscle aches and headaches. **Aspirin**, ibuprofen, and naproxen **sodium** are typically not recommended, as they can increase bleeding problems.

Patients with DHF or dengue shock syndrome may require additional care, possibly in a hospital. Care may include monitoring of blood pressure, intravenous replacement of fluids and electrolytes, and **transfusion** to counter blood loss.

KEY TERMS

Arbovirus—A virus that is transmitted to a host by an insect or other arthropod vector.

Arthropod—An insect or other invertebrate (lacking a backbone) that has an external skeleton (exoskeleton), a segmented body, and jointed appendage.

Petechiae—Small reddish or purplish spots on the skin caused by broken capillaries.

Vector—A carrier organism (such as a fly or mosquito) that delivers a pathogen, such as a virus, to a host.

Prognosis

The prognosis for dengue fever is very good, and almost all patients fully recover. Patients with DHF and/or dengue shock syndrome do best when their illness is identified and treatment is begun as early as possible. As more time passes before treatment is initiated, the likelihood of recovery diminishes. Complications from DHF and dengue shock syndrome vary, but may include seizures, and damage to the brain or to other organs.

Prevention

The best defense against dengue fever is a strong offense against disease-carrying mosquitoes. To accomplish a lowered population of mosquitoes, steps should be taken to eliminate their breeding grounds. This includes draining sources of standing water, such as buckets, vases, and other water-holding vessels. Mosquito repellant is recommended for those areas where dengue fever is endemic.

To help break the cycle of transmission, sick beds should be placed within bed netting so that mosquitoes do cannot bite patients and become arboviral vectors, transmitting the disease to another person.

Dental caries *see* **Tooth decay**

Dental cavity *see* **Tooth decay**

Dental erosion

Definition

Erosion is wearing down of tooth enamel by acids. Tooth enamel is the hard coating that protects teeth and the dentin, the layer just under the enamel that leads to sensitive nerve tissues.

Description

The tooth's enamel is considered the hardest tissue in a human body, enabling people to bite into foods and protecting the sensitive tissues and nerves just below the surface of the teeth. Although enamel is tough, it is clear, and tooth color comes mostly from the layer under the enamel, called the dentin.

Unless a person takes care of the teeth with regular brushing, flossing, and visits to the dentist for cleanings, items such as coffee, tea, and red wine can cause permanent staining of the enamel. Consuming foods and drinks that are acidic can cause even more damage, called dental erosion. Chemical reactions in acids from foods, medications, and the stomach interact with tooth enamel and wear enamel down, usually leaving a smooth, hollowed out appearance.

In minor cases, dental erosion affects the appearance of teeth, causing yellowing. In more severe cases, the erosion wears down the entire layer of enamel and exposes the dentin, making the teeth more sensitive to hot and cold. Dental erosion is different from dental cavities, which are caused by bacteria.

Risk factors

Some wearing down of enamel is normal with **aging**. Acid that wears down tooth enamel can come from within a person's body or from outside of it. For example, the human body's digestive system makes acids to break down foods in the stomach. If a person vomits or regurgitates often, these acids can affect tooth enamel. Some drinks have high levels of citric acids or other acids. When these acids come into contact with tooth enamel frequently or in great quantities, they can cause erosion. Examples of risk factors for dental erosion are:

- excessive consumption of alcohol
- excessive soft drink consumption
- gastroesophageal reflux disease (GERD)
- bulimia
- excessive soft drink consumption
- Excessive consumption of fruit drinks, especially citrus beverages such as lemon and orange juices
- frequent use of some medications, such as aspirin and antihistamines
- hereditary, or genetic, factors
- poor saliva flow, or dry mouth
- more rapid wear from activities such as grinding teeth during sleep

WWW.BOOKBAZ.IR

Demographics

The number of people with dental erosion is increasing in the United States and around the world. Estimates vary but show that up to 82% of the population has some dental erosion. Some studies show that the problem is worse among young people, which means it could increase as they age.

Causes and symptoms

Dental erosion is caused by a chemical reaction between a number of acids and the tooth enamel. Acids that come from foods and drinks include citric, phosphoric, malic, carbonic, tartaric, and absorbic acid. An acid first softens the normally hard enamel and then causes the crystals that make up tooth enamel to dissolve a layer at a time. In advanced cases, the entire enamel coating on a tooth can dissolve completely, reducing the size of the tooth and the protection of dentin.

In addition to diet choices, especially the use of carbonated sodas, both regular and diet, some diseases and conditions can lead to dental erosion. Acid reflux disease, or GERD, causes acids from the stomach to enter the mouth and reach tooth enamel. Frequent **vomiting** from the eating disorder bulimia is one of the major causes of dental erosion. In addition to bringing up stomach acids that cause erosion especially on the inside of the upper front teeth, the vomiting can add to **dry mouth**. Having a dry mouth also increases risk of dental erosion.

A person who has dental erosion may not know that the process is happening or may only notice slight yellowing of some teeth. Once erosion worsens, a smooth, hollowed out area may become apparent on the surface of the tooth. The most obvious and troubling symptoms are from increased sensitivity to hot and cold food and drinks. Because the dentin is exposed, the tooth's pulp, which contains blood vessels and nerves, is closer to the surface and the tooth is more sensitive. A severely eroded tooth can be more open to decay or damage.

Diagnosis

Dentists can observe signs of dental erosion during a dental examination. When a person reports heat and cold sensitivity, the dentist can examine the teeth specifically for signs of dental erosion. Early diagnosis helps dentists work with their patients to prevent further erosion and to treat the problem if necessary.

Treatment

Tooth enamel is not made up of the type of living cells that can repair and regenerate themselves, like fingernail cells, for example. This means that dentists cannot replace enamel, but they can use cosmetic procedures to cover a tooth's surface.

If dental erosion is minor, a dentist may recommend steps to prevent further erosion. If a patient has symptoms such as **pain** and sensitivity, the dentist may recommend bonding or a veneer. Dental bonding is a cosmetic procedure to repair teeth that are stained or cracked. The procedure, which involves matching the look and shade of a stained tooth to other teeth, uses a special resin that adheres to the tooth. The dentist tries to make it look as natural as possible, and bonding works particularly well for front teeth. A veneer is a thin shell made of porcelain that is attached to an existing tooth. The dentist usually can complete the process of matching and placing a veneer in two appointments. In severe cases, the dentist may recommend covering an eroded tooth with a crown to protect the tooth from further erosion.

A crown caps or covers the tooth and usually is made of porcelain or ceramic materials. Often, the procedures used to repair dental erosion require the dentist to roughen or remove some of a patient's tooth so that the cosmetic replacement has a strong surface for attachment. The dentist also may recommend use of certain materials to help slow erosion or ease pain and sensitivity. For example, a dental hygienist may apply a fluoride varnish to the teeth.

Additonal techniques for dental erosion repair are being investigated. One 2012 study reported that a liquid containing **minerals** and a sticky material could help cause enamel and dentin to repair themselves.

Prognosis

If a person who has early signs of erosion addresses the causes and makes changes to diet or other activities that are leading to erosion, the outlook is very good. Dental erosion can be slowed and discoloration can be treated. If a person who has signs and symptoms of dental erosion fails to get help for the pain and sensitivity and the problem worsens, the condition may lead to some loss of tooth function because of damage to the pulp in the center of the tooth.

Prevention

Avoiding foods and beverages with high acid content can help prevent dental erosion. In particular, fruit juices, carbonated sodas, even diet sodas, are

KEY TERMS

Bulimia—Also called bulimia nervosa, an eating disorder characterized by secretly binging, or eating large amounts of food, then purging by vomiting the food or using laxatives, diuretics, or excessive exercise to lose weight.

Dentin—The largest part of the tooth, which lies just below enamel and above the pulp.

Pulp—The part of the tooth where blood vessels and nerves are located.

Regurgitate—Thrown or poured back, usually referring to swallowed food coming back up into the throat and mouth.

high in acids. Using a straw to drink beverages with acid helps push the fluid to the throat, bypassing the teeth and rinsing out the mouth after drinking sodas can help remove remaining acids from the teeth. Replacing sodas and citrus-based beverages with water or milk is an excellent preventive measure. Also tea and coffee without sugar are less acidic. Chewing sugar-free gum also increases saliva production without adding sugar. Using a fluoride toothpaste or gel can help strengthen tooth enamel. As always, regular flossing and brushing with a soft-bristled toothbrush lead to good oral health, including prevention of dental erosion.

Dental fillings

Definition

Dental fillings are metal amalgams or composite resins used to fill a cavity.

Purpose

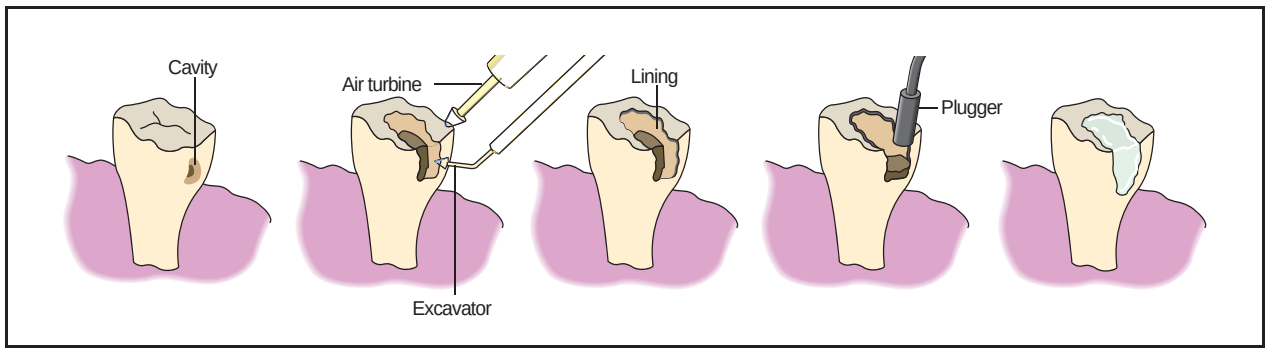
Dentists use dental fillings to restore teeth damaged by dental caries (**tooth decay**). Dental caries are caused by microorganisms that convert sugars in food to acids that erode the enamel of a tooth, creating a hole or cavity. The dentist cleans out the decayed part of the tooth and fills the opening with an artificial material (a filling) to protect the tooth's structure and restore the appearance and utility of the tooth.

Precautions

As in any dental procedure, the dentist and dental assistant will need to use sterile techniques. Gloves and masks are essential as well as the sterilization of equipment and tools. This not only helps prevent the spread of infectious diseases like **AIDS** and hepatitis, but also the **common cold**.

The patient's reaction to **anesthesia** is the other main concern of the dentist and dental assistant when performing dental fillings. Nitrous oxide should be avoided with pregnant patients, and local anesthetics

WWW.BOOKBAZ.IR



The process of filling a cavity. *(Illustration by Hans & Cassady, Inc. © Cengage Learning®.)*

should be used with caution, though they are considered safe. Local anesthetics like Novocain and lidocaine have been in practical use for decades with few side effects reported. Some patients, however, are allergic to these drugs.

Description

When the dentist discovers a cavity, filling options are discussed with the patient. The dental assistant prepares the dentist's workstation and lays out the specific instruments that are needed. The dental assistant prepares the filling material according to the manufacturer's directions and assists the dentist in preparing the tooth for filling and in the filling procedure itself. The dental assistant cleans the patient's mouth and returns the procedure room to order. All of the instruments that have been used are sterilized by the dental assistant.

Though dentists are encountering fewer and smaller cavities in their patients, there is still a need for dentists to fill cavities. Old fillings wear out over time and need to be replaced. Recently, patients have begun to request more restorative work on their teeth, sometimes opting for full mouth restorations that involve installing crowns, bleaching teeth or applying veneers, and replacing dark metal fillings with tooth-colored ones that create a monochromatic view in a patient's mouth.

The dentist begins by removing the decayed area of the tooth and preparing the tooth to receive the filling. The dentist has a wide choice of dental filling materials to choose from.

Amalgam fillings

The most common and strongest filling material is amalgam. It is a silver filling that is usually placed on the rear molars, which endure more stress during chewing. Amalgam fillings—used for large, deep cavities—are strong and very resistant to wear. Amalgam has been in use since 1833.

Amalgam is a mixture (which is what the word means) of several metals, including liquid mercury (35% silver, 15% tin or tin and copper, a trace of zinc, and 50% mercury). When it is prepared, it has a malleable consistency that can easily be shaped to fit the prepared tooth. It hardens to a durable metal.

Despite its durability, many dentists and patients avoid amalgam fillings. Dentists have found that amalgam has a tendency to expand with time. As a result, teeth become fractured from the inside, often splitting the tooth. Patients often avoid amalgam for strictly aesthetic reasons. Amalgam fillings darken over time and make teeth look as if they are decayed.

The biggest reason amalgam has lost favor is a health concern due to its 50% mercury content. Although the American Dental Association (ADA) has pronounced amalgam safe in the quantity and composition of amalgam, some patients and dentists are disturbed by various reports of illness in relation to the mercury in amalgam fillings. Mercury is a toxic material. Some states are required to dispose of mercury waste as if it were a hazardous product. There is also an added risk of inhaling mercury particles when old fillings are removed.

Gold fillings

Gold fillings or inlays are created outside of the mouth by a dental technician and then cemented into place. They are also used to fill the back molars. Gold fillings are very durable. Like amalgam, however, they are not as aesthetically pleasing as tooth-colored fillings.

Composite fillings

Composite fillings, often called white fillings, are made of a plastic resin and finely ground glass. They must be applied to the tooth surface in thin layers.

Dentists try to match the color of composites with neighboring teeth for a more natural look, making the filling appear invisible. Composite resin fillings often are made smaller than amalgam fillings and require less tooth preparation, thereby saving more natural tooth surface.

Composite fillings are bonded to the tooth so that the tooth becomes stronger than it was before. They are also less sensitive to temperature changes in the mouth that can damage the tooth; therefore there is less chance that the tooth will shatter because of the filling.

These fillings may not be suitable for large cavities in molars. Though composite durability increased in the 1990s, a porcelain inlay or crown may be the best choice for a durable, natural-looking restoration of a molar.

The major drawback of composite resin fillings is cost. They average one-and-a-half to two times more than the price of amalgam fillings. They also can be stained from drinking coffee and tea. Large composite fillings tend to wear out sooner than amalgam fillings.

Composite fillings can last seven to 10 years, which is similar to the lifespan of amalgam fillings.

Resin ionomer

Resin ionomers are new, tooth-colored filling materials that contain a resin and fluoride. They are very suitable for children and for older adults who have root decay that is more likely to occur as a person ages. These fillings seal the tooth and also protect it from future decay because of the fluoride that they release.

Preparation

During a routine checkup, the dentist may find a cavity in a tooth with a metal tooth probe. A new diagnostic tool, the DIAGNOdent, can detect evidence of cavities and pre-cavity conditions on the tooth's surface. A low-powered laser, the DIAGNOdent is able to detect decay so early that a dental cavity can be avoided. These pre-cavity areas can be protected with a sealant, thereby preventing further decay.

If the cavities found are relatively small and not very deep, there may be no need to anesthetize the area where the dental work will be done. High-speed drills often are able to clean out the decay quickly and with little discomfort. If the cavity is not very deep, the drill may not reach the sensitive nerves in the teeth, which usually cause **pain**. Children and some adults may need anesthesia in any case. The dentist and the dental assistant need to be aware of the patient's history and if the patient reacts adversely to local anesthesia.

There are some dentists who use electronic dental anesthesia (EDA), a device that sends electrical charges to the gum through electrodes. Sometimes this is enough anesthesia for the procedure. At other times, EDA numbs the area where the anesthesia is administered, so that the patient does not feel the needle as it goes into the gum. Some dentists also provide soothing music to calm patients during the procedure. Other dentists will use local anesthesia in combination with nitrous oxide-oxygen analgesia to minimize discomfort through the drilling phase of a filling.

Dental lasers that generate a low-powered beam of light are being used to cut away decay, but without the whine of the drill and without using anesthesia. Though a bit slower than the conventional drill, lasers are very efficient at preparing a tooth to receive a filling. Unfortunately, lasers cannot yet remove old fillings or prepare a tooth surface to receive a crown.

Air abrasion is another way to remove decay without using anesthesia. Air abrasion machines produce a spray of air and powder. There is no vibration or heat. Because it has no vibration, it avoids microfractures in the tooth that sometimes occur with drills. Air abrasion removes only a small amount of the tooth's structure. Therefore, it is suitable for small cavities and the repair and replacement of old fillings. It also can repair chipped teeth and clean discolored or stained teeth.

After the cavity is cleaned of decay, the walls of the tooth are shaped and are ready to receive a filling material. If a composite resin filling is used, the tooth next needs to be etched so that the resin will adhere to the tooth. The tooth then is filled, shaped, and polished. The composite filling then must be hardened by shining a special light on it.

Aftercare

The dentist and dental assistant should advise the patient that the teeth, lips, and tongue may be numb for several hours after the procedure, if a local anesthetic was used. Some patients experience sore gums or a sensitivity to hot and cold in the tooth that has just been filled. Normally, patients are advised to avoid chewing hard foods directly on new amalgam fillings for 24 hours. Composite fillings require no special caution since they set immediately. If patients experience continued pain or an uncomfortable bite, they should call their dentist.

WWW.BOOKBAZ.IR

KEY TERMS

Amalgam—A mixture of metals, primarily mercury used to make large, durable fillings. Also called silver fillings.

Anesthesia—A condition created by drugs that produces a numb feeling. General anesthesia produces unconsciousness whereas a local anesthesia produces numbness around the site where the drug was introduced.

Composite filling—A resin material that is tooth colored and is used to fill a tooth once decay has been removed. It is used most often in front teeth, but may be used in any tooth for aesthetic reasons.

Crown—An artificial covering prepared by a lab technician to fit over a damaged tooth or one weakened by decay.

Dental caries—Tooth decay caused by microorganisms that convert sugars in food to acids, which erode the enamel of a tooth.

Dental laser—A device that generates a low-powered beam of light that is used in place of a dentist's drill to cut away decay from a tooth or remove gum tissue.

Enamel—The hard outer surface of a tooth.

Risks

Some patient's have allergic reactions to local anesthesia. The tooth that received a filling may be sensitive to changes in temperature or may be sore for a short time after the procedure.

Results

Fillings restore a tooth's function and appearance. They permit the patient to continue to eat and chew properly and last for several years. Normal fillings will need to be replaced over a patient's lifetime. Since fewer dental caries had been observed since the last decade of the twentieth century, dentists are initially filling fewer teeth, but are replacing fillings as they fail and sometimes systematically, especially if the patient decides to cosmetically enhance his or her teeth. Since many of the initial cavities are quite small, patients are opting for more aesthetically pleasing filling materials even if they are not as durable.

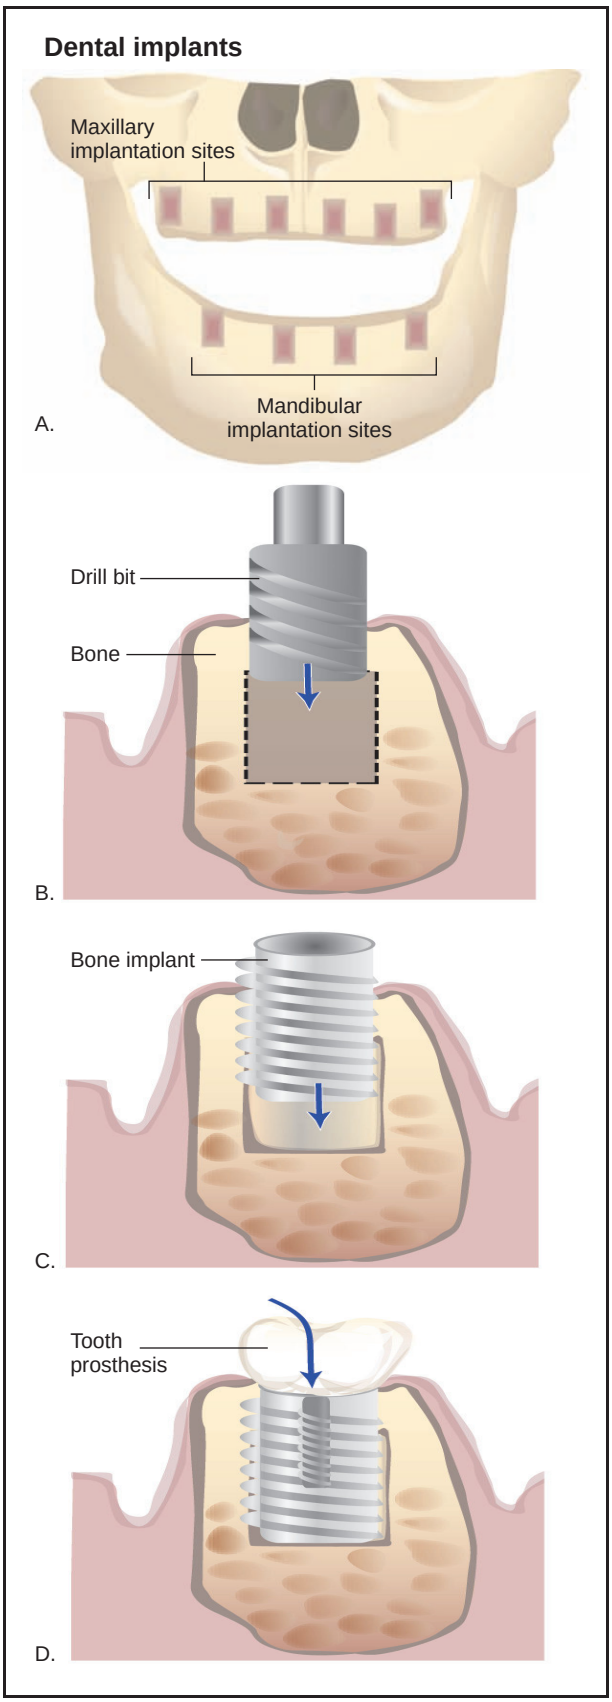
Dental implants and restoration

Definition

Dental implants are surgically fixed substitutes for roots of missing teeth. Embedded in the jawbone, they act as anchors for a replacement tooth, also known as a crown, or a full set of replacement teeth. These artificial devices, which appear similar to a natural tooth root, are usually made of titanium. Though looking comparable to natural roots, dental implants will feel slightly different from natural teeth when chewing food.

Purpose

The purpose of dental implant surgery is to position metallic anchors in the jawbone so that they can receive the replacement teeth and hold them in place. Dental implants should be considered as an option for



A dental drill is used to make a hole for the implant in the jawbone (B). The bone implant is secured into the drilled hole (C), and the tooth prosthesis is built onto the implant (D). *(Illustration by PreMediaGlobal. © Cengage Learning®.)*

replacing failing or missing teeth and often provide more predictable results than bridgework, resin bonded bridges, or endodontic treatment.

Demographics

According to the American Association of Oral and Maxillofacial Surgeons (AAOMS), almost 70% of adults ages 35–44 have lost at least one tooth, and 26% of adults lose all of their teeth by age 74.

According to the American Academy of Implant Dentistry, in 2010, 1.3 million dental implants were performed in the United States. Dental implants are equally popular in Europe, especially in Germany, where the procedure is reimbursed by the national healthcare system.

Description

By replacing a lost tooth with a dental implant, the overall health and function of the surrounding teeth is maintained. The implant can prevent tooth migration and loss of structure and will help avoid loss of bone from the jaw in that area. Further, implants reduce the impact of the lost tooth on surrounding teeth, as traditional bridge structures often require reduction (filing down) of the two flanking teeth to hold the bridge in place with a crown. Implanting avoids such alterations to the surrounding teeth when replacing a lost tooth.

When replacing dentures, implants can provide even more benefits. Implants do not slip nor do they have the potential of limiting the diet to easily chewed foods as can happen with poorly fitting dentures. If appropriate, implants are the method most able to surgically restore one or more missing teeth to their original conditions.

Under local **anesthesia**, the first step for most implant procedures is the exposure of the bone where the implant is to be made. This is followed by placement of the implant into the exposed jawbone. Implants that are placed in the bone are called endosteal implants and are made of titanium or a titanium alloy because this metal does not adversely interact with biological tissue. After placement of the implant, a cover screw is put in and the wound is closed with stitches and allowed to heal. In general, placements in the lower jaw need to heal about three months, while placements in the upper jaw need to heal about six months.

WWW.BOOKBAZ.IR

After healing, in a second surgical procedure, the implant is uncovered, the cover screw is removed, and a healing abutment or a temporary crown is placed in the implant. Temporary crowns are generally used for aesthetic reasons when the implant is in a place that is visible. Both healing abutments and temporary crowns allow the tissue around the implant to be trained to grow around the final prosthetic tooth.

After about two months, the soft tissue will be healed enough to receive the final prosthetic tooth. Impressions are used to make custom abutments that take into account the neck morphology of the implant. The prosthetic tooth is sometimes attached to a gold cylinder that can be screwed into the abutment or it can be directly cemented onto the abutment. This multi-stage process, where the two surgical procedures are separated by a lengthy healing time, has proven to provide excellent stability in the final implant. Single-step surgical implants are available, but some stability of the final implant is often lost by eliminating the healing step.

Preparation

Implants can be done by dentists, periodontists, or oral surgeons. The procedure is done in the dental professional's office.

At the first appointment, the dentist or oral surgeon performs a thorough examination to determine whether implants are appropriate to replace the missing teeth. X-rays are often necessary to discover the state of the jawbone, particularly if the teeth have been lost for some time. This information is used to determine if implants are appropriate and, if so, what particular type of implant would be best for the clinical situation.

There are two solutions commonly used if the initial examination indicates that the bone in the area where the implant is to occur is too resorbed to support the implant. The first is **bone grafting**. This involves undergoing a procedure that moves bone from one place in the body to another to enlarge the bone structure at the implant site. Often, bone can be moved from one place in the mouth to another. Sometimes a graft from a donor, or an animal, or artificial bone can be used if bone from the patient is not available. Grafting usually is done four to eight months before the implant procedure to allow the graft a chance to heal before it is disturbed with the implant process.

A second solution is the use of subperiosteal implants that ride above the bone but beneath the gum. These types of implants are not placed in the bone. A computed tomography (CT) scan is commonly used to obtain a model of the bone structure and then the implant fixture is molded to precisely fit the bone model.

Aftercare

After a dental implant, it is recommended not to eat until the general anesthetic has worn off. Only cold drinks should be consumed during this time, and they should be taken in small amounts. Avoid all hot drinks and foods during the first 24 hours after the procedure. In addition, do not **exercise** vigorously for 48 hours afterwards.

Some swelling will probably occur, especially in the mornings after sleeping horizontally all night. The swelling should diminish within two days of the procedure. Bleeding is common after such a procedure. Apply pressure for 30 minutes to stop any bleeding. Bruising of the skin will probably be noticed, but it should go away over a few days. Swelling can be reduced with ice packs wrapped in a towel, held onto the area for no more than 10 minutes at a time, with a 20-minute break between each application. After one day, warmth—such as from a heating pad—will help the healing process. The area will be sore for a few days. Take a **pain** reliever after the anesthetic has worn off. Ask the attending doctor for dosage amounts. Continuing pain after three or four days should be reported to a medical professional.

Risks

The greatest risk following the surgical procedures is that the implant will fail. For implants placed within the bone, most failures occur within the first year and then occur at a rate of less than 1% per year thereafter. Recent research has indicated that tobacco use by the patient and use of a single-stage implant procedure are two risk factors that increase failure rates.

Results

Overall, the success rate for all implants is 90–95%. Most failed implants can be replaced with a second attempt.

According to the AAOMS, the risk of complications from dental implants is generally less than 5%. Many medical studies report failure rates from 7% to 10%. This low rate of complications is mostly due to the high professionalism of the medical professional implanting them, along with the quality and the quantity of the bone at the implant site. Most problems that do occur are minor in nature and are easily corrected. Complications can increase, however, when users do not use good **oral hygiene** after receiving dental implants, which is further increased when their overall health is not good. In such cases, minor problems that are not treated properly can eventually

KEY TERMS

Computed tomography (CT) scan—A method of imaging both hard and soft tissue of the body; it is used to visualize the placement of dental implants that are not within the bone.

Crown—An artificial replacement tooth.

Endosteal implants—Dental implants that are placed within the bone.

Prosthetic tooth—The final tooth that is held in place by the dental implant anchor.

Resorbed—Absorbed by the body because of lack of function. This happens to the jawbone after tooth loss.

cause major problems including the failure of such implants.

Alternatives

Although no alternatives totally replace dental implants, four options are available: dental bridge, partial denture, complete denture, and treatment delay. A dental bridge is kept in place with the use of the neighboring teeth. Some of the surfaces of the healthy neighboring teeth are ground down to help in affixing the replacement teeth. A partial denture consists of a plastic tooth positioned on a plastic retainer. These removable, fragile dentures are usually non-permanent but provide a low-cost, short-term option to dental implants.

Complete dentures are another option instead of dental implants. They are, however, sometimes considered by users to be uncomfortable. Complete dentures also have a reputation for falling out of the mouth if they become loosened. However, with proper maintenance they can be an adequate and affordable substitute for dental implants when more or all of the teeth are missing. Some people will simply delay dental implants as much as possible. The delay can have detrimental consequences to the jawbone and the tissue surrounding the bone. This is because the structure and shape of the jawbone can change over time when teeth are missing. Overall, delaying dental implants is the least expensive alternative.

Dental sealants

Definition

A dental sealant is a thin layer of plastic substance that is painted over teeth to discourage the formation of dental caries (cavities).

Demographics

Dental sealants normally are applied to the permanent back teeth (pre-molars and molars) of children soon after these teeth erupt through the gum, most often between the ages of six and 12 years. In a 2005 study, the U.S. Centers for Disease Control and Prevention (CDC) found that only 32% of children aged 6–19 years had received dental sealants. One of the goals of the U.S. Department of Health and Human Services Initiative Healthy People 2010 is to increase the percentage of children who receive dental sealants to 50%.

Purpose

The purpose of applying dental sealants is to protect the teeth by sealing out food particles and acids produced by bacteria so that they do not accumulate on the tooth surface and cause decay.

Description

Dental sealants, sometimes called tooth sealants, are plastic material that first appeared in the 1960s. Sealants usually are applied to the chewing teeth—the pre-molars and molars. These are teeth that have what dentists call "pits and fissures" or rough surfaces with deep grooves that a toothbrush has trouble cleaning.

Teeth continuously develop a coating plaque that consists of bacteria and mucin. In order to prevent **tooth decay**, plaque must be removed daily through brushing and flossing. The structure of the pre-molars and molars makes it very difficult to reach all surfaces with a toothbrush. When dental sealant is applied to these teeth, it protects the tooth enamel from plaque. This helps prevent tooth decay and may ultimately save the individual money by eliminating the need for fillings, crowns, or other treatment for tooth decay. Some dental insurance will pay for sealants but may put restrictions on when or to which teeth they may be applied. Individuals should check with their insurance company.

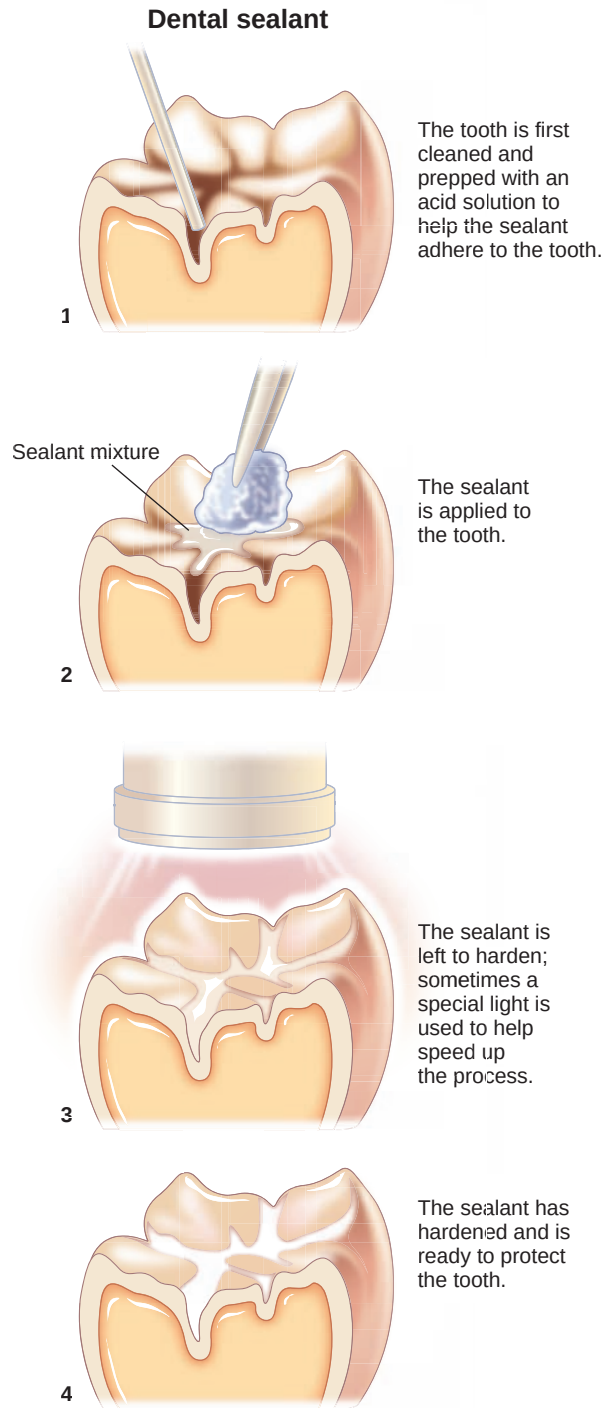

Illustration showing how a dental sealant is applied. *(Illustration by Electronic Illustrators Group. © Cengage Learning®.)*

Dental sealants can be applied quickly and painlessly. The procedure is as follows:

- The tooth is cleaned and dried.
- An acid solution is painted on the tooth in order to roughen the surface so that the dental sealant adheres to the tooth better.
- The tooth is rinsed and dried.
- A liquid sealant is applied to the tooth.
- The sealant quickly hardens

In March 2008, the American Dental Association (ADA) made the following recommendations based on critical evaluation of studies conducted on dental sealants (evidence based medicine):

- Sealants should be placed on pits and fissures of children's and adolescent's permanent teeth when these teeth are at risk for developing dental caries.
- Sealants should be placed on teeth early before cavities develop.
- Resin-based sealants are the preferred type of sealant.

The expert committee appointed by the ADA to investigate sealants suggested that sealants be placed on adult teeth in danger of developing dental caries, However, studies of sealants in adults have not been adequate to make this a firm, evidence-based recommendation. The use of sealants in primary (baby) teeth is left to the discretion of the dentist and the parent.

KEY TERMS

Cavity—A hole or weak spot in the tooth surface caused by decay.

Dental caries—The medical term for tooth decay.

Enamel—The hard, outermost surface of a tooth.

Evidence-based medicine—Recommendations that are based on an evaluation of randomized, controlled trials; non-randomized trials; other experiments; descriptive studies; and reports of expert committees. Each class of evidence is graded (A to D, with A being the most reliable) based on the type and size of study. Recommendations and clinical practice guides can then be made using these grades.

Fluoride—A chemical compound containing fluorine that is used to treat water or applied directly to teeth to prevent decay.

Mucin—A protein in saliva that combines with sugars in the mouth to form plaque.

Plaque—A thin, sticky, colorless film that forms on teeth. Plaque is composed of mucin, sugars from food, and bacteria that live in the plaque.

Benefits

There is clear evidence that sealant applied when secondary pre-molars or molars erupt from the gum will reduce the likelihood of developing dental caries in these teeth. Adults may have sealants applied, but the benefit to adults has not been proven.

Precautions

The tooth must be free of decay before the sealant is applied. If tooth decay has already begun, there exists the possibility that they tooth will continue to decay under the sealant and that this will not be detected until much damage has already been done.

The sealant material may contain small amounts of bisphenol A (BPA), a material found in plastics that has been shown to cause cancer in animals. As of 2010, the ADA has stated that BPA is rarely used in dental sealants and that the small amount that may be present should not cause health concerns. Some European countries and Canada are considerably more concerned about the health risks of BPA than the United States. They are more likely to regulate the use of this material.

Preparation

The tooth is examined for any sign of decay. If no decay is found, the tooth is cleaned before the sealant is applied. If there is any sign of dental caries, the sealant should not be applied; instead, the decay should be removed and the tooth filled.

Aftercare

Sealants harden very quickly. No aftercare is needed. Sealants last on average five to ten years.

Risks

There are no known risks related to the application of dental sealants except for the concerns mentioned in the Precautions section.

WWW.BOOKBAZ.IR

Research and general acceptance

The ADA and most other dental associations in developed countries endorse the use of dental sealants on secondary pre-molars and molars of children. Use of sealants in adults and on primary teeth of children is not specifically endorsed, but is left up to the discretion of the dentist and the patient.

Holistic dentists tend to be less enthusiastic about the use of dental sealants, citing concerns about trapping decay in the tooth and the presence of BPA in the sealant material.

Training and certification

Sealants are applied by a licensed dentist, often with the assistance of a certified dental hygienist.

Dental trauma

Definition

Dental **trauma** is injury to the mouth, including teeth, lips, gums, tongue, and jawbones. The most common dental trauma is a broken or lost tooth.

Description

Dental trauma may be inflicted in a number of ways: contact sports, motor vehicle accidents, fights, falls, eating hard foods, drinking hot liquids, and other such mishaps. As oral tissues are highly sensitive, injuries to the mouth are typically very painful. Dental trauma should receive prompt treatment from a dentist.

Causes and symptoms

Soft tissue injuries, such as a "fat lip," a burned tongue, or a cut inside the cheek, are characterized by **pain**, redness, and swelling with or without bleeding. A broken tooth often has a sharp edge that may cut the tongue and cheek. Depending on the position of the fracture, the tooth may or may not cause **toothache** pain. When a tooth is knocked out (evulsed), the socket is swollen, painful, and bloody. A jawbone may be broken if the upper and lower teeth no longer fit together properly (**malocclusion**), or if the jaws have pain with limited ability to open and close (mobility), especially around the temporomandibular joint (TMJ).

Diagnosis

Dental trauma is readily apparent upon examination. Dental x rays may be taken to determine the extent of the damage to broken teeth. More comprehensive x rays are needed to diagnose a broken jaw.

Treatment

Soft tissue injuries may require only cold compresses to reduce swelling. Bleeding may be controlled with direct pressure applied with clean gauze. Deep lacerations and punctures may require stitches. Pain may be managed with **aspirin** or **acetaminophen** (Tylenol, Aspirin Free Excedrin) or ibuprofen (Motrin, Advil).

Treatment of a broken tooth will vary depending on the severity of the fracture. For immediate **first aid**, the injured tooth and surrounding area should be rinsed gently with warm water to remove dirt, then

covered with a cold compress to reduce swelling and ease pain. A dentist should examine the injury as soon as possible. Any pieces from the broken tooth should be saved and brought along.

If a piece of the outer tooth has chipped off, but the inner core (pulp) is undisturbed, the dentist may simply smooth the rough edges or replace the missing section with a small composite filling. In some cases, a fragment of broken tooth may be bonded back into place. If enough tooth is missing to compromise the entire tooth structure, but the pulp is not permanently damaged, the tooth will require a protective coverage with a gold or porcelain crown. If the pulp has been seriously damaged, the tooth will require **root canal treatment** before it receives a crown. A tooth, that is vertically fractured or fractured below the gumline will require root canal treatment and protective restoration. A tooth that no longer has enough remaining structure to retain a crown may have to be extracted (surgically removed).

When a permanent tooth has been knocked out, it may be saved with prompt action. The tooth must be found immediately after it has been lost. It should be picked up by the natural crown (the top part covered by hard enamel). It must not be handled by the root. If the tooth is dirty, it may be gently rinsed under running water. It should never be scrubbed, and it should never be washed with soap, toothpaste, mouthwash, or other chemicals. The tooth should not be dried or wrapped in a tissue or cloth. It must be kept moist at all times.

The tooth may be placed in a clean container of milk, cool water with or without a pinch of salt, or in saliva. If possible, the patient and the tooth should be brought to the dentist within 30 minutes of the tooth loss. Rapid action improves the chances of successful re-implantation; however, it is possible to save a tooth after 30 minutes, if the tooth has been kept moist and handled properly.

The body usually rejects re-implantation of a primary (baby) tooth. In this case, the empty socket is treated as a soft tissue injury and monitored until the permanent tooth erupts.

A broken jaw must be set back into its proper position and stabilized with wires while it heals. Healing may take six weeks or longer, depending on the patient's age and the severity of the fracture.

Alternatives

There is no substitute for treatment by a dentist or other medical professional. There are, however, homeopathic remedies and herbs that can be used simultaneously with dental care and throughout the healing process. Homeopathic arnica (*Arnica montana*) should be taken as soon as possible after the injury to help the body deal with the trauma. Repeating a dose several times daily for the duration of healing is also useful. Homeopathic hypericum (*Hypericum perforatum*) can be taken if nerve pain is involved, especially with a **tooth extraction** or root canal. Homeopathic comfrey (officinale) *Symphytum* may be helpful in treating pain due to broken jaw bones, but should only be used after the bones have been reset. Calendula (*Calendula officinalis*) and plantain (*Plantago major*) can be used as a mouth rinse to enhance tissue healing. These herbs should not be used with deep lacerations that need to heal from the inside first.

KEY TERMS

Crown—The natural part of the tooth covered by enamel. A restorative crown is a protective shell that fits over a tooth.

Eruption—The process of a tooth breaking through the gum tissue to grow into place in the mouth.

Evulsion—The forceful, and usually accidental, removal of a tooth from its socket in the bone.

Extraction—The surgical removal of a tooth from its socket in the bone.

Malocclusion—A problem in the way the upper and lower teeth fit together in biting or chewing.

Pulp—The soft innermost layer of a tooth containing blood vessels and nerves.

Root canal treatment—The process of removing diseased or damaged pulp from a tooth, then filling and sealing the pulp chamber and root canals.

Temporomandibular joint (TMJ)—The jaw joint formed by the mandible (lower jaw bone) moving against the temporal (temple and side) bone of the skull.

Prognosis

When dental trauma receives timely attention and proper treatment, the prognosis for healing is good. As with other types of trauma, infection may be a complication, but a course of **antibiotics** is generally effective.

WWW.BOOKBAZ.IR

Prevention

Most dental trauma is preventable. Car seat belts should always be worn, and young children should be secured in appropriate car seats. Homes should be monitored for potential tripping and slipping hazards. Child-proofing measures should be taken, especially for toddlers. In addition to placing gates across stairs and padding sharp table edges, electrical cords should be tucked away. Young children may receive severe oral **burns** from gnawing on live power cords.

Everyone who participates in contact sports should wear a mouthguard to avoid dental trauma. Athletes in football, ice hockey, wrestling, and boxing commonly wear mouthguards. The mandatory use of mouthguards in football prevents about 200,000 oral injuries annually. Mouthguards should also be worn along with helmets in noncontact sports such as skateboarding, in-line skating, and bicycling. An athlete who does not wear a mouthguard is 60 times more likely to sustain dental trauma than one who does. Any activity involving speed, an increased chance of falling, and potential contact with a hard piece of equipment has the likelihood of dental trauma that may be prevented or substantially reduced in severity with the use of mouthguards.

Bethany Thivierge

Dental x rays

Definition

Dental x rays are pictures taken of the mouth area using high-energy photons with very short wavelengths. They show the teeth and surrounding bone.

Purpose

Dental x rays are part of the dental examination for aiding in the diagnostic process. They are effective in discovering **tooth decay**, broken fillings, fractured teeth, tumors, occlusal **trauma**, or impacted or ectopic teeth that would otherwise be unseen by the eye. X rays are vital in the diagnosis of **root canal treatment** on checking the end of the tooth's root (apical) and the surrounding structures for abscesses or bone loss. Without the aid of dental x rays, 60% of dental decay would be missed.

Description

William Roentgen, a German scientist, discovered the x-ray in 1895. He found that x rays are energy in the form of waves, similar to visible light. The only difference between light and x rays is that light does not have the ability to penetrate the body as x-ray energy does. Light makes pictures of the outside of objects, while x rays have the ability to make pictures of the inside of objects.

Dental x rays pass through hard and soft tissue in the mouth. The x-ray beam is blocked by denser structures, such as teeth, fillings, jaws, and bones. Teeth appear lighter because fewer x rays go through the teeth to reach the film. Cavities and gum disease appear darker (shown by a dark spot in the tooth or loss of bone structure around the tooth) because of more x-ray penetration. On the film, the white images are the dense structures.

Types of dental x rays

The most common x-rays taken are:

- bitewing x rays (vertical and horizontal bitewings)
- panoramic x rays
- periapical x rays
- occlusal x rays

BITEWING. The bitewing x ray is the most common. Bitewings are the most effective in discovering tooth decay in between the teeth and on adjacent teeth. A bitewing shows only the top crown portion of the tooth structure. It is called a bitewing due to the way the patient bites down and holds the film securely in place. The bitewing is good in diagnosing and evaluating periodontal conditions and bone levels between the teeth. Bitewing x rays are also good in detecting tartar buildup.

PANORAMIC. The panoramic (a type of film used), or Panorex (brand name), is also commonly taken on the initial visit to a dental office. This type of

x ray makes a complete circle of the head from one ear to the other to produce a complete two-dimensional representation of all the teeth. This x ray also shows bone structure beneath the teeth and the temporomandibular joint (TMJ). The panoramic is the most commonly used x-ray in the aid of diagnostic decisions regarding third molar extractions (wisdom teeth) for people who are edentulous (the tooth is not there/has not erupted).

The panoramic x ray has its advantages and disadvantages. It images a broad area, showing many structures, and the exposure level emits low radiation. The panoramic is excellent for evaluation of trauma, tooth development, and certain anomalies. In some cases, dental x rays can even reveal non-dental medical conditions. One study at the University of Buffalo School of Dental Medicine demonstrated that calcifications in the carotid arteries, which were exposed on standard panoramic x rays, served as predictors of death from cardiovascular disease.

The main disadvantage of panoramic x rays is that the image shown does not provide the fine detail of a bitewing x ray. The procedure for taking a panoramic x ray is also somewhat confining to the patient, as the x-ray machine takes a minute or more to fully encircle the head for the complete picture. These films are not good in aiding the diagnosis of decay, bone level, and certain types of periapical problems.

PERIAPICAL. A periapical x ray is similar to a bitewing. This type of x ray shows the entire tooth area, from crown to root, and the bone surrounding the root from a side view. This type of film will reveal any root anomalies, changes in the bone and surrounding tissue, cysts, bone tumors, and abscesses. The fine detail in the periapical film is necessary in diagnosis and treatment planning, and is commonly taken during root canal treatment and crown restoration procedures.

OCCLUSAL. Occlusal films are least common. These films show the whole bite of the lower or upper jaw. Occlusal x rays, when taken, are mainly taken on children to show the eruption order of the permanent teeth.

X-ray units

The roentgen (R) represents the amount of exposure given off by one single energy photon. The amount of absorbed x ray in the body is a unit called a rad. A unit called "rem" accounts for the difference in biological effectiveness of different types of radiation, such as secondary radiation or cosmic radiation. One rem equals one rad. One rad equals one R and one thousand milliroentgens (mrad); it is equal to one roentgen.

A registered dental assistant (RDA) or registered dental hygienist (RDH) commonly takes the x rays during a dental examination. They review the health and dental history, chart, and age of the patient to be x-rayed. Adjustments are made to the x-ray unit depending on the size and age of the patient. The RDA then develops and mounts the x rays and presents them to the dentist. The dentist will interpret the x rays and complete the oral examination. A treatment plan will follow.

An RDA and an RDH must have an x-ray certification in order to take and develop x-rays. To become certified, full-mouth sets of x-rays need to be taken. Knowledge of the x-ray machine unit is needed, as is the number of roentgens emitted from a variety of different x-ray machines. Furthermore, a working knowledge of angles and height of the x-ray unit is needed; this is necessary for taking fine-detailed images. Certification also requires knowledge of the principles of radiation safety.

Classes leading to certification as an RDA or RDH are available outside the work setting. Each state has different bylaws regarding x-ray licensing for technicians. The rules of the state in which one is interested in working should be consulted.

KEY TERMS

Apical—Rounded end of the root of a tooth that is embedded in hard tissue (bone); toward the apex of the root.

Crown—The upper part of the tooth, covered by enamel; also, a dental restoration that is a protective shell fitting over a tooth.

Eruption—The process of a tooth breaking through the gum tissue to grow into place in the mouth.

Periapical—Referring to the tissue surrounding the apex of a tooth's root.

Pulp—The soft, innermost part of a tooth containing blood and lymph vessels, and nerves.

Root canal treatment—The process of removing diseased or damaged pulp tissue from a tooth, then filling and sealing the pulp chamber and root canals.

WWW.BOOKBAZ.IR

Diagnosis

Dental x rays are essential in diagnosing and treating oral disease, abnormal tooth development, or trauma. At the initial dental examination, a full-mouth set of x rays may be taken (bitewings and panoramic). Thereafter, it is the dentist who should determine when and how often x rays will be required. Children are usually more cavity prone than adults; x rays may be taken with regard to degree of risk, or at the check-up examination every six months.

An adult presenting a **dental trauma** will need x rays to diagnose what the treatment should be. More x rays may be needed depending on the treatment plan and the extent of the injury.

Aftercare

There is no aftercare necessary after receiving dental x-rays. Patients may wish to schedule their next dental appointment within six months. The American Dental Association (ADA) recommends basic guidelines on the frequency of dental x rays. On average, bitewing x rays should be taken approximately once a year. This is mainly to detect and treat any conditions early in their development. If the overall general health of the mouth is good, x rays can be taken every 18 to 24 months. The ADA also recommends that the type and frequency of dental x rays taken at an examination be based upon clinical judgment after the examination and consideration of the dental health and the general health of the patient.

Risks

The primary concern associated with any type of x-ray is adverse effects from radiation. Research conducted by the Idaho Radiation Network set a maximum permissible x ray dose for one year at 5R (roentgens). A full mouth set of dental x rays consists of 18 to 20 films (bitewings, periapicals, occlusals, and panoramic x rays). The amount of radiation for receiving the full-mouth set of x rays is 10–20 mrads. The benefits derived from x rays greatly outweigh the radiation concerns. The amount of radiation an average person receives each year from background sources (e.g., outer space, materials in the earth, foods consumed, and naturally radioactive materials in the body) is about 360 mrads.

Secondary radiation consists of the radiation waves left over after the source of radiation is stopped. Most secondary waves can penetrate tissue and are the most damaging waves from radiation. Measures taken to prevent damaging rays include:

- setting radiation exposure to lower settings depending on the patient's age, height, and body type
- using high-speed films to minimize exposure time
- using lead-filled aprons to shield sensitive body parts, such as thyroid glands and gonads
- x-ray badges worn by dental staff to monitor the amount of radiation exposure in the workplace

Results

The x rays are available almost immediately for the dentist to review. If abnormalities are present, patients will be informed at their examination and will not have to wait to learn the results.

Depo-Provera/Norplant

Definition

Medroxyprogesterone is a long-acting progestin hormone that is inserted under the skin and prevents conception for up to five years. Depo-Provera is also a hormone, but is administered by intramuscular injection and provides protection against **pregnancy** for three months. Lunelle is another injectable contraceptive that is administered monthly (every 28 to 30 days); it was approved by the Food and Drug Administration (FDA) in October 2000. The hormone in Norplant and Depo-Provera is progestin, a synthetic hormone similar to one found naturally in a woman's body; Lunelle contains the hormones progestin and estrogen.

A physician inserts a contraceptive implant under the skin of a woman's arm. *(Photo Researchers, Inc.)*

Purpose

The purpose of these hormones is to prevent pregnancy; they are about 99% effective in achieving this goal. No hormonal contraceptive methods provide protection from **AIDS** or other sexually transmitted diseases.

Depo-Provera and Lunelle are given as an injection and work in several ways to prevent conception. First, the egg (ovum) is prevented from maturing and being released. The mucus in the cervix (opening into the uterus or womb) becomes thicker, making it difficult for the sperm to enter. Depo-Provera and Lunelle also cause the lining of the uterus to become thinner, making implantation of a fertilized egg unlikely.

An injection of Depo-Provera or Lunelle must be given within the first five days of a normal period. Depo-Provera provides protection against pregnancy for three months, while Lunelle provides similar protection for one month. Ovulation (release of a mature egg) typically occurs within 60 days of the last injection of Lunelle, about twice as fast after use of Depo-Provera. Also, because Lunelle is a combined hormone contraceptive as opposed to progestin-only Depo-Provera and Norplant, it is less likely to cause irregular or absent menstruation.

Norplant capsules contain a synthetic hormone that is slowly released over a period of up to five years. It functions like Depo-Provera in that it prevents the ovaries from producing ova (eggs) and also results in thicker mucus in the cervix, which prevents the sperm from passing through the cervix. Norplant can be inserted at any time.

Preparation

The woman being considered for Depo-Provera or Lunelle will have a pelvic and breast examination, a **Pap test** (a microscopic examination of cell samples taken from the cervix), blood pressure check, weight check, and a review of her medical history. Women who have **diabetes mellitus**, major depression, blood clotting problems, **liver disease**, or weight problems should use these methods only under strict medical supervision. Depo-Provera or Lunelle should not be used if the woman is pregnant, has unexplained

WWW.BOOKBAZ.IR

KEY TERMS

Cervix—Narrow, lower end of the uterus forming the opening to the vagina.

Hormone—A chemical produced in a gland or organ and transported by the blood to another area of the body where it produces a specific effect.

Pap test—A microscopic examination of cell samples taken from the cervix.

Uterus—The female reproductive organ that contains and nourishes a fetus from implantation until birth.

vaginal bleeding, suffers from severe liver disease, has **breast cancer**, or has a history of **blood clots** or **stroke**.

Individuals who select Norplant will receive the same basic **physical examination**. If approved for this method, a site of implantation will be selected (usually the inside of the upper arm), and the area prepared for minor surgery. The skin will be washed with soap and water, and an antiseptic, such as iodine solution, will be applied. The physician will use a local anesthetic to numb the area, a small incision will be made, the six Norplant capsules will be inserted, and the incision sewn up (sutured). Protection against pregnancy normally begins within 24 hours. If necessary, the implants can be removed in 15–20 minutes. Norplant should not be used by women who are pregnant, have blood clotting problems, or have unexplained vaginal bleeding. Advantages include light periods with less cramping and decreased anemia. This form of birth control may also be protective against **endometrial cancer**.

Because Depo-Provera and Norplant use only the hormone progestin, they may provide an alternative for women who can not use estrogen-containing birth control pills. One benefit of Lunelle, however, is that its effects wear off more quickly than Depo-Provera, an important factor in the event that a woman has serious side effects or wants to become pregnant.

Risks

The most common side effects associated with Depo-Provera and Lunelle are yellowing of the skin, **headache**, nervousness, **dizziness**, abdominal **pain**, hair loss, rash, increase in the number of migraine headaches, increased or decreased interest in sexual intercourse, the development of dark spots on the skin, depression, and weakness; more serious is, liver disease and breast cancer. Danger signs that need to reported immediately include weight gain, heavy vaginal bleeding, frequent urination, blurred vision, **fainting**, severe abdominal pain, and coughing up blood. Because the effects of Depo-Provera may last up to 12 weeks, it may take a longer time for women trying to conceive to become pregnant after discontinuing the injections.

The main reactions to Norplant include headache, weight gain, irregular periods or no period at all, breast tenderness, **acne**, gain or loss of facial hair, color changes of the skin over the area of insertion, and **ovarian cysts**. The doctor should be notified immediately of lumps in the breast, heavy vaginal bleeding, yellowing of the skin or eyes, or infection of the incision. Women who use Norplant are discouraged from **smoking**.

As of 2010, Depo-Provera comes with a special warning that links prolonged use of the drug with bone density loss. The Food and Drug Administration's strident warning informs women that the drug can cause significant loss of bone density. Losses are greater when the drug is used longer. In addition, bone density loss may not reverse completely when women stop using Depo-Provera. The FDA's decision to add such a warning followed analyses by the agency and Pfizer of data about the drug's long-term effect on bone density among teens and adult women. The women's study ran from 1994 to 2010 and enrolled 540 women aged 25 to 38.

Results

These hormone contraceptive methods normally result in a success rate of 99%.

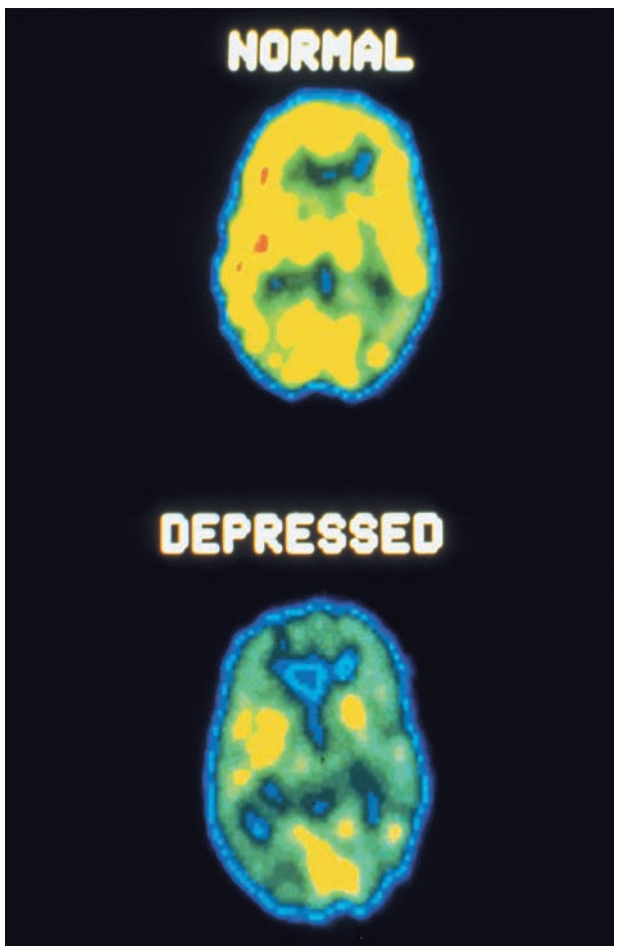
Depressive disorders

Definition

Depression or depressive disorders (unipolar depression) are mental illnesses characterized by a profound and persistent feeling of sadness or despair and/or a loss of interest in things that once were pleasurable. Disturbance in sleep, appetite, and mental processes are a common accompaniment.

Description

Everyone experiences feelings of unhappiness and sadness occasionally. But when these depressed feelings start to dominate everyday life and cause physical and mental deterioration, they become what are known as depressive disorders. There are two main categories of depressive disorders: major depressive disorder and dysthymic disorder. Major depressive disorder is a moderate to severe episode of depression lasting two or more weeks. Individuals experiencing this major depressive episode may have trouble sleeping, lose interest in activities they once took pleasure in, experience a change in weight, have difficulty concentrating, feel worthless and hopeless, or have a preoccupation with death or **suicide**. In children, major depression may be characterized by irritability.



Positron emission tomography (PET) scans comparing a normal brain with that of someone with a depressed mental disorder. *(Photo Researchers, Inc.)*

The National Institutes of Mental Health estimated that about 6.7% of Americans adults are affected by major depressive disorder, and about 1.5% are affected by dyrthmic disorder in a given year. Major depressive disorder has a median age of onset of 32 years, and affects women more frequently than men. Dyrthmic disorder has a median age of onset of 31 years. Both disorders may occur in any age group, from children to the elderly.

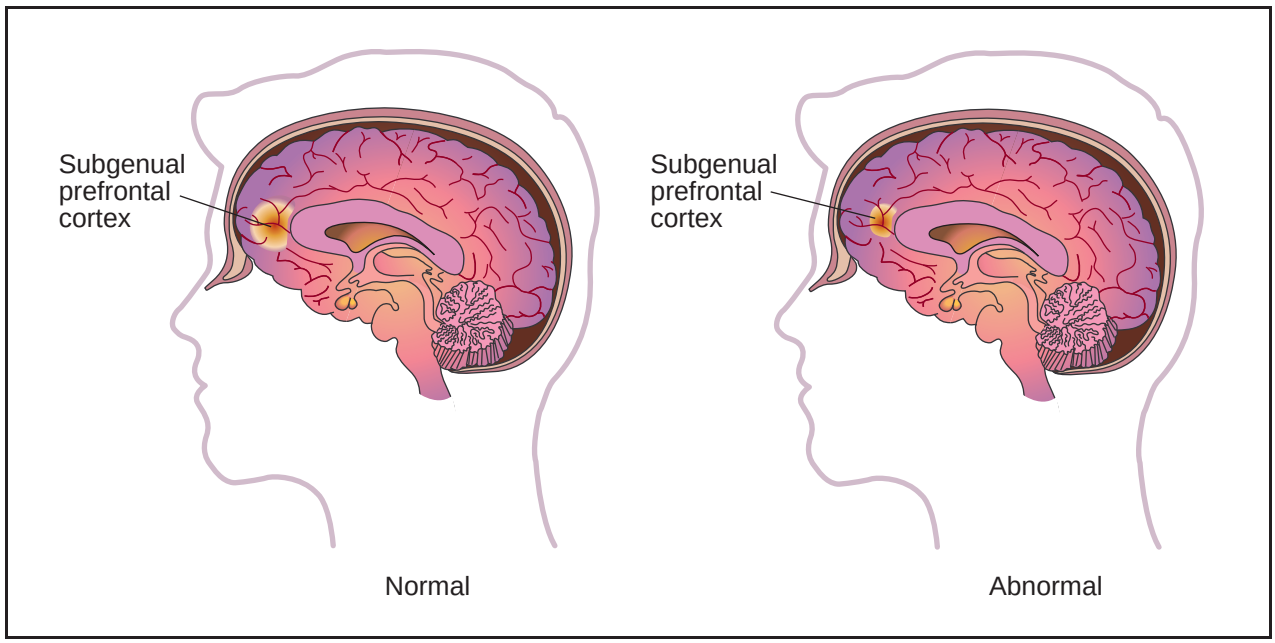
While major depressive episodes may be acute (intense but short-lived), dysthymic disorder is an ongoing, chronic depression that lasts two or more years (one or more years in children) and has an average duration of 16 years. The mild to moderate depression of dysthymic disorder may rise and fall in intensity, and those afflicted with the disorder may experience some periods of normal, non-depressed mood of up to two months in length. Its onset is gradual, and dysthymic patients may not be able to pinpoint exactly when they started feeling depressed. Individuals with dysthymic disorder may experience a change in sleeping and eating patterns, low self-esteem, **fatigue**, trouble concentrating, and feelings of hopelessness.

Depression also can occur in **bipolar disorder**, an affective mental illness that causes radical emotional changes and mood swings, from manic highs to depressive lows. The majority of bipolar individuals experience alternating episodes of **mania** and depression.

Causes and symptoms

The causes behind depression are complex and not yet fully understood. While an imbalance of certain neurotransmitters—the chemicals in the brain that transmit messages between nerve cells—is believed to play a key role in depression, external factors such as upbringing and environment (more so in dysthymia than major depression) may be as important. For example, it is speculated that, if an individual is abused and neglected throughout

WWW.BOOKBAZ.IR



Recent scientific research has indicated that the size of the subgenual prefrontal cortex of the brain (located behind the bridge of the nose) may be a determining factor in hereditary depressive disorders. *(Illustration by Electronic Illustrators Group. © Cengage Learning®.)*

childhood and adolescence, a pattern of low self-esteem and negative thinking may emerge. From that, a lifelong pattern of depression may follow. Many different factors have been linked to major depression, including chronic **pain**, severe **obesity**, and **smoking** (among teenagers).

Heredity seems to play a role in who develops depressive disorders. Individuals with major depression in their immediate family are up to three times more likely to have the disorder themselves. It would seem that biological and genetic factors may make certain individuals pre-disposed or prone to depressive disorders, but environmental circumstances often may trigger the disorder.

External stressors and significant life changes, such as chronic medical problems, death of a loved one, divorce or estrangement, **miscarriage**, or loss of a job, also can result in a form of depression known as adjustment disorder. Although periods of adjustment disorder usually resolve themselves, occasionally they may evolve into a major depressive disorder.

Major depressive episode

Individuals experiencing a major depressive episode have a depressed mood and/or a diminished interest or pleasure in activities. Children experiencing a major depressive episode may appear or feel irritable rather than depressed. In addition, five or more of the following symptoms will occur on an almost daily basis for a period of at least two weeks:

- Significant change in weight.
- Insomnia or hypersomnia (excessive sleep).
- Psychomotor agitation or retardation.
- Fatigue or loss of energy.
- Feelings of worthlessness or inappropriate guilt.
- Diminished ability to think or to concentrate, or indecisiveness.
- Recurrent thoughts of death or suicide and/or suicide attempts.

Dysthymic disorder

Dysthymia commonly occurs in tandem with other psychiatric and physical conditions. Up to 70% of dysthymic patients have both dysthymic disorder and major depressive disorder, known as double depression. Substance abuse, panic disorders, **personality disorders**, social **phobias**, and other psychiatric conditions also are found in many dysthymic patients. Dysthymia and medical conditions often co-occur. The connection between them is unclear, but it may be related to the way the medical condition and/or its pharmacological treatment affects neurotransmitters. Dysthymia is prevalent in patients with **multiple**

Signs of depression

Lack of interest or pleasure in daily activities
Significant weight loss (without dieting) or weight gain
Difficulty sleeping or excessive sleeping
Loss of energy
Feelings of worthlessness or guilt
Difficulty in making decisions
Restlessness
Recurrent thoughts of death

sclerosis, **AIDS**, **hypothyroidism**, **chronic fatigue syndrome**, Parkinson's disease, diabetes, and post-cardiac transplantation. Dysthymic disorder can lengthen or complicate the recovery of patients with these and other medical conditions.

Along with an underlying feeling of depression, people with dysthymic disorder experience two or more of the following symptoms on an almost daily basis for a period for two or more years (many experience them for five or more years), or one year or more for children:

- under or overeating
- insomnia or hypersomnia
- low energy or fatigue
- low self-esteem
- poor concentration or trouble making decisions
- feelings of hopelessness

Diagnosis

In addition to an interview, several clinical inventories or scales may be used to assess a patient's mental status and determine the presence of depressive symptoms. Among these tests are: the Hamilton Depression Scale (HAM-D), Child Depression Inventory (CDI), Geriatric Depression Scale (GDS), Beck Depression Inventory (BDI), and the Zung Self-Rating Scale for Depression. These tests may be administered in an outpatient or hospital setting by a general practitioner, social worker, psychiatrist, or psychologist.

Treatment

Major depressive and dysthymic disorders are typically treated with a combination of antidepressants and psychosocial therapy. Psychosocial therapy focuses on the personal and interpersonal issues behind depression, while antidepressant medication is prescribed to provide more immediate relief for the symptoms of the disorder. When used together correctly, therapy and antidepressants are a powerful treatment plan for the depressed patient.

Antidepressants

Selective serotonin reuptake inhibitors (SSRIs) such as fluoxetine (Prozac) and sertraline (Zoloft) reduce depression by increasing levels of serotonin, a neurotransmitter. Some clinicians prefer SSRIs for treatment of dysthymic disorder. **Anxiety**, **diarrhea**, drowsiness, **headache**, sweating, nausea, poor sexual functioning, and **insomnia** all are possible side effects of SSRIs. In early 2004, the U.S. Food and Drug Administration (FDA) issued warnings to physicians and parents about increased risk of suicide among children and adolescents taking SSRIs.

Tricyclic antidepressants (TCAs) are less expensive than SSRIs, but have more severe side-effects, which may include persistent **dry mouth**, **sedation**, **dizziness**, and cardiac **arrhythmias**. Because of these side effects, caution is taken when prescribing TCAs to elderly patients. TCAs include amitriptyline (Elavil), imipramine (Tofranil), and nortriptyline (Aventyl, Pamelor). A 10-day supply of TCAs can be lethal if ingested all at once, so these drugs may not be a preferred treatment option for patients at risk for suicide.

Monoamine oxidase inhibitors (MAOIs) such as tranylcypromine (Parnate) and phenelzine (Nardil) block the action of monoamine oxidase (MAO), an enzyme in the central nervous system. Patients taking MAOIs must cut foods high in tyramine (found in aged cheeses and meats) out of their diet to avoid potentially serious hypertensive side effects.

Heterocyclics include bupropion (Wellbutrin) and trazodone (Desyrel). Bupropion should not be prescribed to patients with a **seizure disorder**. Side effects of the drug may include agitation, anxiety, confusion, tremor, dry mouth, fast or irregular heartbeat, headache, low blood pressure, and insomnia. Because trazodone has a sedative effect, it is useful in treating depressed patients with insomnia. Other possible side effects of trazodone include dry mouth, gastrointestinal distress, dizziness, and headache.

Psychosocial therapy

Psychotherapy explores an individual's life to bring to light possible contributing causes of the present depression. During treatment, the therapist helps the patient to become self-aware of his or her thinking patterns and how they came to be. There are

WWW.BOOKBAZ.IR

several different subtypes of psychotherapy, but all have the common goal of helping the patient develop healthy problem solving and coping skills.

Cognitive-behavioral therapy assumes that the patient's problematic thinking is causing the current depression and focuses on changing the depressed patient's thought patterns and perceptions. The therapist helps the patient identify negative or distorted thought patterns and the emotions and the behaviors that accompany them, and then retrains the depressed individual to recognize the thinking and react differently to it.

Electroconvulsant therapy

ECT, or **electroconvulsive therapy**, usually is employed after all psychosocial therapy and pharmaceutical treatment options have been explored. However, it is sometimes used early in treatment when severe depression is present and the patient refuses oral medication, or when the patient is becoming dehydrated, extremely suicidal, or psychotic.

The treatment consists of a series of electrical pulses that move into the brain through electrodes on the patient's head. ECT is given under general **anesthesia** and patients are administered a muscle relaxant to prevent convulsions. Although the exact mechanisms behind the success of ECT therapy are not known, it is believed that the electrical current modifies the electrochemical processes of the brain, consequently relieving depression. Headaches, muscle soreness, nausea, and confusion are possible side effects immediately following an ECT procedure. **Memory loss**, typically transient, also has been reported in ECT patients.

Alternatives

St. John's wort (*Hypericum perforatum*) is used throughout Europe to treat depressive symptoms. Unlike traditional prescription antidepressants, this herbal antidepressant has few reported side effects. Despite uncertainty concerning its effectiveness, it is accepted by many practitioners of alternative medicine. Although St. John's wort appears to be a safe alternative to conventional antidepressants, care should be taken, as the herb can interfere with the actions of some pharmaceuticals, and because herbal supplements are not regulated by the FDA in the same way as conventional medications.

Homeopathic treatment also can be therapeutic in treating depression. Good **nutrition**, proper sleep, **exercise**, and full engagement in life are very important to a healthy mental state.

In several small studies, S-adenosyl-methionine (SAM, SAMe) was shown to be more effective than placebo and equally effective as tricyclic antidepressants in treating depression. The usual dosage is 200–400 mg twice daily. It may however cause some side effects, and an individual should discuss the possible risks and benefits with a doctor.

KEY TERMS

Hypersomnia—The need to sleep excessively; a symptom of dysthymic and major depressive disorder.

Neurotransmitter—A chemical in the brain that transmits messages between neurons, or nerve cells. Changes in the levels of certain neurotransmitters, such as serotonin, norepinephrine, and dopamine, are thought to be related to depressive disorders.

Psychomotor agitation—Disturbed physical and mental processes (e.g., fidgeting, wringing of hands, racing thoughts); a symptom of major depressive disorder.

Psychomotor retardation—Slowed physical and mental processes (e.g., slowed thinking, walking, and talking); a symptom of major depressive disorder.

Prognosis

Untreated or improperly treated depression is the number one cause of suicide in the United States. Proper treatment relieves symptoms in 80–90% of depressed patients. After each major depressive episode, the risk of recurrence climbs significantly—50% after one episode, 70% after two episodes, and 90% after three episodes. For this reason, patients need to be aware of the symptoms of recurring depression and may require long-term maintenance treatment of antidepressants and/or therapy.

Research has found that depression may lead to other problems as well. Increased risk of **heart disease** has been linked to depression, particularly in postmenopausal women. And while chronic pain may cause depression, some studies indicate that depression may also cause chronic pain.

Prevention

Patient education in the form of therapy or self-help groups is crucial for training patients with depressive disorders to recognize symptoms of depression and to take an active part in their treatment program. Extended maintenance treatment with antidepressants may be required in some patients to prevent relapse. Early intervention for children with depression is usually effective in arresting development of more severe problems.

Dermatitis

Definition

Dermatitis is a general term used to describe different types of skin inflammation. The different types of inflammation of the skin all have a common factor: an allergic reaction to specific allergens. Thus, the condition is characterized by an itchy rash found on reddened, swollen skin. Although not a serious condition, not life threatening, and not always contagious to others, dermatitis usually makes the person feel uncomfortable due to its itchy nature.

Description

Most types of dermatitis are characterized by an itchy pink or red rash with the likely presence of blisters, oozing, or flaking and/or crusting skin. **Contact dermatitis**, stasis dermatitis, nummular dermatitis, **atopic dermatitis**, and **seborrheic dermatitis** are five types of the condition that inflame the skin.

Contact dermatitis

Contact dermatitis, which includes allergic contact dermatitis and irritant contact dermatitis, is an allergic reaction to something that irritates the skin and is manifested by one or more lines of red, swollen, blistered skin that may itch or seep. It usually appears within 48 hours after touching or brushing against a substance to which the skin is sensitive. The condition is more common in adults than in children.

This type of dermatitis can occur on any part of the body, but it usually affects the hands, feet, and

Dermatitis on hands and fingers. *(Custom Medical Stock Photo, Inc.)*

WWW.BOOKBAZ.IR

groin. Contact dermatitis usually does not spread from one person to another, nor does it spread beyond the area exposed to the irritant. However, in the case of some irritants, such as **poison ivy**, contact dermatitis can be passed to another person or to another part of the body. Poison ivy is an example of allergic contact dermatitis, one in which a skin allergy occurs when something touches the skin, even for a brief moment. Plants, such as flowers, fruits, herbs, and vegetables, can also cause allergic contact dermatitis, as can metals, rubber, and fragrances. Irritant contact dermatitis is often a problem when individuals wash their hands many times a day, which causes the skin to dry out, eventually damaging it.

Stasis dermatitis

Stasis dermatitis is characterized by scaly, greasy-looking skin on the lower extremities, especially the lower legs and around the ankles. Stasis dermatitis is most apt to affect the inner side of the calf. It is often a precursor to more serious problems such as venous leg ulceration. This type of dermatitis is more likely to affect middle-aged and elderly people. It only rarely occurs among those under 50 years of age. However, when it does occur in younger people, it is usually caused by surgery, thrombosis, or **trauma**. Complications from stasis dermatitis includes **cellulitis** and various non-healing venous **ulcers**.

Nummular dermatitis

Nummular dermatitis, which is also called nummular eczematous dermatitis or nummular **eczema**, generally affects the hands, arms, legs, and buttocks of people over 55 years of age. Although most common at this age and older, it can appear at any age. This stubborn inflamed rash forms circular or oval-shaped, sometimes itchy, red patches (lesions) and is characterized by flares and periods of inactivity. It is not contagious and is not believed to be genetic or related to **food allergies**. Nummular dermatitis can be brought on by **stress** or excessive use of **caffeine**, a substance that dehydrates the body, thus making the skin drier than normal.

Atopic dermatitis

Atopic dermatitis, commonly called eczema, is characterized by **itching**, scaling, swelling, and sometimes blistering. When occurring in early childhood, it is called infantile eczema and is characterized by redness (or yellowness), oozing, and crusting. It is usually found on the face, inside the elbows, and behind the knees. Atopic dermatitis is often found on people who have **allergies**, **asthma**, or have excessive stress in their lives.

Seborrheic dermatitis

Seborrheic dermatitis may be dry or moist and is characterized by greasy scales and yellowish crusts on the scalp, eyelids, face, external surfaces of the ears, underarms, breasts, and groin. In infants it is called cradle cap. In adults, it is known as dandruff.

Demographics

Work-related skin diseases are especially common in certain industrial occupations. Most occupational skin diseases involve dermatitis. About 9.8% of U.S. workers (approximately 15.2 million) in 2010 were afflicted with dermatitis. It was found more frequently among female workers than male workers. Further, people with a college degree or those with some college had higher rates of dermatitis than those with a high school degree or those without such a degree. Specific industries had higher rates than did others. The highest rates of dermatitis were reported in the areas of healthcare and social assistance and life, physical, and social science.

Causes and symptoms

Allergic reactions are genetically determined, and different substances cause contact dermatitis to develop in different people. A reaction to resin produced by poison ivy, **poison oak**, or poison sumac is the most common source of symptoms. It is, in fact, the most common allergy in this country, affecting one of every two people in the United States.

Flowers, herbs, and vegetables can also affect the skin of some people. **Burns** and **sunburn** increase the risk of dermatitis developing. Chemical irritants can cause the condition, too. These include:

- chlorine
- cleansers
- detergents and soaps
- fabric softeners
- glues used on artificial nails
- perfumes
- topical medications

Contact dermatitis can develop when the first contact occurs or after years of use or exposure. It occurs commonly on areas of the body that come into contact with substances that irritate the skin, such as poison ivy. People who wear jewelry made of nickel often are afflicted with contact dermatitis.

Certain cleaning products, cosmetics, and perfumes can cause this type of dermatitis.

Stasis dermatitis, a consequence of poor circulation, occurs when leg veins can no longer return blood to the heart as efficiently as they once did. When this happens, fluid collects in the lower legs and causes them to swell. Stasis dermatitis can also result in a rash that can break down into sores known as stasis ulcers.

The cause of nummular dermatitis is not known, but it usually occurs in cold weather and is most common in people who have dry skin. Hot weather and stress can aggravate this condition, as can the following:

- allergies
- fabric softeners
- soaps and detergents
- wool clothing
- bathing more than once a day

Atopic dermatitis can be caused by allergies, asthma, or stress, and there seems to be a genetic predisposition for atopic conditions. Thus, it often occurs in families that have asthma, eczema, or hay **fever**. It is sometimes caused by an allergy to nickel in jewelry. It begins with a red-itchy rash and occurs in areas where the skin moves frequently such as inside the elbows, in the front of the neck, and behind the knees.

Seborrheic dermatitis (for which there may also be a genetic predisposition) is usually caused by overproduction of the oil glands. In adults, it can be associated with **diabetes mellitus** or an allergy to gold. In infants and adults, it may be caused by a biotin deficiency. It frequently produces dandruff.

Diagnosis

The diagnosis of dermatitis is made on the basis of how the rash looks and its location. The doctor may scrape off a small piece of affected skin for microscopic examination or direct the patient to discontinue use of any potential irritant that has recently touched the affected area. Two weeks after the rash disappears, the patient may resume use of the substances, one at a time, until the condition recurs. Eliminating the substance most recently added should eliminate the irritation.

If the origin of the irritation has still not been identified, a dermatologist may perform one or more patch tests. This involves dabbing a small amount of a suspected irritant onto skin, often times on the patient's back. If no irritation develops within a few days, another patch test is performed. The process continues until the patient experiences an allergic reaction at the spot where the irritant was applied.

Treatment

Treating contact dermatitis begins with eliminating or avoiding the source of irritation. Prescription or over-the-counter corticosteroid creams can lessen inflammation and relieve irritation. Creams, lotions, or ointments not specifically formulated for dermatitis can intensify the irritation. Oral **antihistamines** are sometimes recommended to alleviate itching, and **antibiotics** are prescribed if the rash becomes infected. Medications taken by mouth to relieve symptoms of dermatitis can make skin red and scaly and cause hair loss.

Patients who have a history of dermatitis should remove their rings before washing their hands. They should use bath oils or glycerin-based soaps and bathe in lukewarm saltwater.

Patting rather than rubbing the skin after bathing and thoroughly massaging lubricating lotion or nonprescription cortisone creams into still-damp skin can soothe red, irritated nummular dermatitis. Highly concentrated cortisone preparations should not be applied to the face, armpits, groin, or rectal area. Periodic medical monitoring is necessary to detect side effects in patients who use such preparations on **rashes** covering large areas of the body.

Coal-tar salves can help relieve symptoms of nummular dermatitis that have not responded to other treatments, but these ointments have an unpleasant odor and stain clothing.

Patients who have stasis dermatitis should elevate their legs as often as possible and sleep with a pillow between the lower legs. Tar or zinc paste may also be used to treat stasis dermatitis. Because these compounds must remain in contact with the rash for as long as two weeks, the paste and bandages must be applied by a nurse or a doctor.

Coal-tar shampoos may be used for seborrheic dermatitis that occurs on the scalp. Sun exposure after the use of these shampoos should be avoided because the risk of sunburn of the scalp is increased.

Light therapy may be useful in the treatment of some types of dermatitis. People should check with a medical professional to see if controlled amounts of natural or artificial light may be helpful in treating their dermatitis.

WWW.BOOKBAZ.IR

Alternatives

Some herbal therapies can be useful for skin conditions. Among the herbs most often recommended are the following:

- Burdock root (*Arctium lappa*)
- Calendula (*Calendula officinalis*) ointment
- Chamomile (*Matricaria recutita*) ointment
- Cleavers (*Galium* ssp.)
- Evening primrose oil (*Oenothera biennis*)
- Nettles (*Urtica dioica*)

Contact dermatitis can be treated botanically and homeopathically. Grindelia (*Grindelia* spp.) and sassafras (*Sassafras albidum*) can help when applied topically. Determining the source of the problem and eliminating it is essential. Oatmeal baths are very helpful in relieving the itch. Bentonite clay packs or any mudpack draws the fluid out and helps dry up the lesions. Cortisone creams are not recommended.

Stasis dermatitis should be treated by a trained practitioner. This condition responds well to topical herbal therapies; however, the cause must also be addressed. Selenium-based shampoos, topical applications of flax oil and/or olive oil, and biotin supplementation are among the therapies recommended for seborrheic dermatitis.

Prognosis

Dermatitis is often chronic, but symptoms can generally be controlled. Increased risk in developing dermatitis comes with age, in people with allergies and asthma, and certain occupations such as those involving cleaning supplies, metals, and solvents. Complications can occur in the form of open sores, which can become infected. If left untreated they may spread and cause life-threatening conditions.

Prevention

Contact dermatitis can be prevented by avoiding the source of irritation. If the irritant cannot be avoided completely, people should wear gloves and other protective clothing whenever exposure is likely to occur.

Immediately washing the exposed area with soap and water can stem allergic reactions to poison ivy, poison oak, or poison sumac, but because soaps can dry the skin, people susceptible to dermatitis should use them only on the face, feet, genitals, and underarms.

KEY TERMS

Allergic reaction—An inappropriate or exaggerated genetically determined reaction to a chemical that occurs only on the second or subsequent exposures to the offending agent, after the first contact has sensitized the body.

Biotin—A B-vitamin, vitamin B_7, also called vitamin H or coenzyme R.

Corticosteriod—A group of synthetic hormones that are used to prevent or reduce inflammation. Toxic effects may result from rapid withdrawal after prolonged use or from continued use of large doses.

Patch test—A skin test that is done to identify allergens. A suspected substance is applied to the skin. After 24–48 hours, if the area is red and swollen, the test is positive for that substance. If no reaction occurs, another substance is applied. This is continued until the patient experiences an allergic reaction at the site where the irritant was applied to the skin.

Rash—A spotted, pink or red skin eruption that may be accompanied by itching and is caused by disease, contact with an allergen, food ingestion, or drug reaction.

Ulcer—An open sore on the skin, resulting from tissue destruction, that is usually accompanied by redness, pain, or infection.

Clothing should be loose fitting and 100% cotton. New clothing should be washed in dye-free, unscented detergent before being worn. Fabric softeners should be avoided.

Injury to the lower leg can cause stasis dermatitis to ulcerate (form open sores). If stasis ulcers develop, a doctor should be notified immediately.

Yoga and other relaxation techniques may help prevent atopic dermatitis caused by stress. Avoidance of sweating may aid in preventing seborrheic dermatitis. Individuals who have dermatitis should also notify a doctor if any of the following occurs:

- fever develops
- skin oozes or other signs of infection appear
- symptoms do not begin to subside after seven days' treatment
- they come into contact with someone who has a wart, cold sore, or other viral skin infection

Generally, cool, wet compresses can help relieve itching. **Bandages and dressings** provide protection to the affected skin. Wearing gloves at night and trimming nails to avoid scratching irritated areas during sleep is helpful. Skin should be moisturized while still damp, for example, just after a shower or bath. Gently drying the skin with a towel after bathing is helpful. Avoiding the use of excessive or hard motions while drying the skin is also helpful. People should bathe in warm, not hot, water. Further, less bathing can help to relieve dry skin. Showering every other day or even less frequently helps relieve and prevent dermatitis. Limiting bathing time to less than 20 minutes is a good idea.

REVISED BY WILLIAM A. ATKINS, B.B., B.S., M.B.A.

Dermatomyositis

Definition

Dermatomyositis (DM) is a rare inflammatory muscle disease that leads to destruction of muscle tissue usually accompanied by **pain** and weakness.

Description

Dermatomyositis is one of a group of three related diseases called inflammatory **myopathies**. The other two are **polymyositis** and inclusion-body **myositis**. These diseases are rare; only about 20,000 people in the United States have DM. Another estimates suggest that DM occurs in about 5.5 individuals out of every one million. The disease is of unknown origin and can develop in children and adults. Most often individuals either develop DM either between the ages of five and 14 or they do not develop it until they are over age 45. In all age groups, females are twice as likely to develop the disease than males. Although DM causes pain and weakness, it is not necessarily life threatening. However, adults, but not children, who develop DM have an increased risk of developing cancer and should be screened for malignancies regularly.

Causes and symptoms

The exact cause of DM is unknown. It is an autoimmune disease. In a healthy body, cells of immune system attack only foreign or defective cells in the body to protect it from disease. In an autoimmune disease, the immune system attacks normal body cells. In the case of DM, immune system cells attack healthy cells of small blood vessels in the muscle and skin. Over time, this causes muscle fiber to shrink and sometimes cuts off blood supply to the muscle. DM tends to develop in muscles closest to the center of the body.

As yet, there is no clear explanation of what causes an individual to develop DM. It is thought

WWW.BOOKBAZ.IR

that the disease may be triggered by a virus or exposure to certain drugs or vaccines. According to the **Muscular Dystrophy** Association, recent research suggests developing DM may be related to the mixing of blood cells that sometimes occurs between the mother and fetus during **pregnancy**. The disease is not directly inherited, although there may be some genetic sensitivity toward whatever triggers it.

Often the first sign of DM is the development of a patchy, scaly, violet to dark red skin rash on the face, neck, shoulders, upper chest, knees, or back. Often the rash appears before any signs of illness or muscle weakness. About 40% of children and teens develop hard, painful bumps under the skin that are deposits of **calcium**, a mineral used in bone formation. This condition, called calcinosis, is much less common in adults.

Muscle weakness, especially in the upper arms, hips, thighs, and neck, becomes apparent in activities such as climbing stairs or reaching up over the head. This weakness develops after the rash appears. Some people have difficulty swallowing and chewing when the muscles of the face and esophagus are affected. Individuals may also feel tried, weak, have a low-grade **fever**, weight loss, and joint stiffness. Some individuals have the rash for years before they progress to these symptoms, while in others the onset of symptoms is rapid. In children the development of symptoms is almost always gradual, making diagnosis especially difficult.

Diagnosis

DM can be difficult to diagnose, and often the first doctor an individual sees is a dermatologist for treatment of the rash and then is referred to a rheumatologist, specialist in internal medicine or neurologist when DM is suspected. Many tests may be done to rule out other diseases before a firm diagnosis is made. A blood test is done to measure the level of creatine kinase. Creatine kinase is an enzyme found in muscle tissue. When muscle is damaged, this enzyme leaks out into the blood. An increased level of creatine kinase in the blood suggests DM as a possible diagnosis. Another blood test may be done to test for specific immune system antibodies. Antibodies are proteins made in response to material the body thinks is foreign.

An electromyogram (EMG) is a test that measures electrical activity in muscles as they contract. Individuals with inflammatory myopathies usually have distinct patterns of electrical activity in the affected muscles. However, up to 15% of people with DM have normal electromyogram readings, so this test is not definitive. The definitive test is a muscle biopsy. The doctor takes a small sample of muscle tissue and examines it under a microscope. From this sample, the doctor can differentiate DM from other inflammatory myopathies and other muscle wasting diseases.

KEY TERMS

Immunoglobulin—Material containing specific antibodies to fight disease that can be injected into an individual to fight infection.

Inflammation—An infection or irritation of a tissue.

Myopathy—Relating to muscle tissue.

Treatment

The goal of treatment is to improve muscle strength and allow the individual to participate in normal daily activities. Individuals are given steroid drugs (prednisone, **corticosteroids**) that suppress the immune system. Over time, these drugs often produce undesirable side effects, so treatment is usually begun with a large dose, then tapered to the minimum dose needed for maintenance. People who do not respond well to steroid treatment may be treated with other immunosuppressive drugs or intravenous immunoglobulin. Individuals with DM are advised to avoid exposure to the sun, as sunlight worsens the skin rash. **Physical therapy** is often helpful in keeping joints from stiffening and freezing. Moderate **exercise** is also recommended.

Alternatives

A healthy diet is recommended for all individuals with supplemental protein for those with severe muscle damage.

Prognosis

The course of DM is highly variable. In about 20% of people, the disease spontaneously goes into remission and individuals are able to lead symptom-free lives for long periods. On the other hand, in about 5% of individuals the disease progresses to death because of heart and lung involvement. The majority of people continue to have some symptoms and require long-term treatment, but their degree of daily activity varies greatly.

Serious complications from DM include involvement of the muscles of the heart and lungs, difficulty eating and swallowing, and a tendency to develop cancer. This association is seen only in adults and not in children. Individuals over age 60 are more likely to have serious complications than younger individuals.

Prevention

There is no known way to prevent this disease.

DES exposure

Definition

DES (diethylstilbestrol) is a hormone that was prescribed for pregnant women in the 1950s and early 1960s. Many years later, doctors discovered that the daughters of the women who received DES were at high risk for a variety of problems, including **infertility**, **premature labor**, and cancer of the vagina and cervix. Sons of DES mothers were also affected.

Demographics

It is estimated that five to 10 million people in the United States were exposed to DES between 1938 and 1971. The United States has approximately 250,000 to one million DES daughters.

Description

In the 1950s and early 1960s, several drug companies claimed that DES (diethylstilbestrol) could prevent miscarriages. DES is a synthetic hormone, related to estrogen. At the time, up to 20% of all pregnancies ended in **miscarriage**, making this an important breakthrough and DES was prescribed for many women who had bleeding in early **pregnancy**. Ultimately, it was found to have no effect on miscarriages and the practice of prescribing DES was stopped in the 1960s. Almost 10 years later, the daughters of women who had taken DES during pregnancy began to develop unusual symptoms.

Doctors discovered that when these young women reached their teens, they were at higher risk for a variety of problems, including:

- clear cell adenocarcinoma of the vagina and cervix
- infertility
- premature labor and other problems in pregnancy

Sons of DES mothers were also affected, although fertility issues are not as common among DES sons as in DES daughters. Sons of DES mothers are more likely to be diagnosed with:

- increased rate of cryptorchidism (undescended testicles)
- increased incidence of epididymal cysts
- increased incidence of hypoplastic testes

Causes and symptoms

DES has affected a very specific group of women. These are women who were exposed to DES in utero before 18 weeks of pregnancy. In other words, their mothers must have taken DES within the first four-to-five months of pregnancy. It is now known that the female reproductive organs are formed during that time. DES appears to interfere with proper growth and development of the uterus, cervix, vagina, and fallopian tubes. In some studies, DES was also associated with a modestly increased risk of **breast cancer** for DES mothers.

In the early 1970s, there was an increase in a rare form of cancer, clear cell adenocarcinoma of the

WWW.BOOKBAZ.IR

vagina and cervix. Up until that time, doctors had seen these cancers only in elderly women. Suddenly, young women who had the disease appeared.

Researchers studied these women to see if they had anything in common. After extensive questioning and examination, it was found that all of the young women had been exposed to DES in utero in the early weeks of pregnancy.

It was a shocking discovery. Doctors had only recently recognized that medications and exposure to chemicals during pregnancy could cause **birth defects**. This was a birth defect that had gone undetected for almost two decades.

Since then, doctors have studied DES daughters very carefully. Fortunately, the risk of clear cell adenocarcinoma is actually quite low. In fact, it appears that if a DES daughter has not developed this cancer by age 30, she will not develop it. Since all DES daughters are now over age 30, there should be no further cases related to DES exposure. However, there are a number of other symptoms and problems associated with DES exposure.

- Cervix and vagina. DES daughters often have distinctive changes of the cervix and vagina that can be seen during a pelvic exam. These changes include a cervical hood (a vaginal fold draped over the cervix), cockscomb cervix (an abnormally shaped cervix), and adenosis (glandular cells normally located within the cervix that appear on the outside of the cervix and in the vagina).
- Fallopian tubes. Some DES daughters have fallopian tube abnormalities that lead to infertility.
- Uterus. Many DES daughters have a uterus that is abnormal in size and shape. The classic sign is the T-shaped uterus. In the normal uterus, the cavity (hollow space inside) is rounded. In a T-shaped uterus, the cavity is reduced to a thin T. The abnormal shape of the inside of the uterus makes it harder for a woman to get pregnant and leads to a higher risk of premature labor and birth.

Diagnosis

Women who have been exposed to DES should have a **pelvic exam** at least once a year. In addition to the usual pelvic exam and Pap smear, DES daughters should have Pap smears of the vagina and, if possible, **colposcopy**. During colposcopy, the doctor looks at the cervix and vagina through a special magnifying scope. In this way, tiny areas of abnormal cells can be seen. This procedure is easily performed in the doctor's office.

KEY TERMS

Cervix—The opening at the bottom of the uterus.

Colposcopy—A special examination of the cervix using a magnifying scope. This is a procedure that can be done in the doctor's office.

Fallopian tubes—The tubes that carry the ovum (egg) from the ovary to the uterus.

Pap smear—A screening test for precancerous and cancerous cells on the cervix. This simple test is done during a routine pelvic exam and involves scraping cells from the cervix.

When DES daughters get pregnant, they may be at high risk for premature labor and birth and should be monitored very carefully.

Not all women who were exposed to DES develop problems in pregnancy. However, if problems like infertility or miscarriage occur, the doctor may recommend a special x-ray test to check the woman's fallopian tubes and uterus. This special test is called a hysterosalpingogram.

Treatment

There is no treatment for the abnormalities of the fallopian tubes and uterus caused by DES exposure. Fortunately, there are treatments that can help with infertility and premature labor. Clear cell adenocarcinoma of the vagina or cervix must be treated with surgery and, possibly, **chemotherapy**.

Prevention

The practice of prescribing DES to prevent miscarriages has been banned in the United States for about five decades. Individuals, especially women, who were exposed to DES in utero, should notify their health care providers and should continue to be monitored.

The Centers for Disease Control and other agencies around the world continue to monitor the women who were prescribed DES and their offspring, including the third generation (grandchildren of the original mothers prescribed DES), to determine the effects, if any, of DES exposure on successive generations.

Detoxification

Definition

Detoxification is one of the more widely used treatments and concepts in alternative medicine. It is based on the principle that illnesses can be caused by the accumulation of toxic substances (toxins) in the body. Eliminating existing toxins and avoiding new toxins are essential parts of the healing process. Detoxification utilizes a variety of tests and techniques.

Purpose

Detoxification is helpful for those patients who have chronic diseases and conditions, including **allergies**, **anxiety**, arthritis, **asthma**, chronic infections, depression, diabetes, headaches, **heart disease**, high **cholesterol**, low blood sugar levels, digestive disorders, mental illness, and **obesity**. It is helpful for those with conditions that are influenced by environmental factors, such as cancer, as well as for those who have been exposed to high levels of toxic materials due to accident or occupation. Detoxification therapy is useful for those with allergies or immune system problems that conventional medicine is unable to diagnose or treat, including **chronic fatigue syndrome**, environmental illness/multiple chemical sensitivity, and **fibromyalgia**. Symptoms for these conditions may include unexplained **fatigue**, increased allergies, hypersensitivity to common materials, intolerance to certain foods and **indigestion**, aches and pains, low grade **fever**, headaches, **insomnia**, depression, sore throats, sudden weight loss or gain, lowered resistance to infection, general malaise, and disability. Detoxification can be used as a beneficial preventative measure and as a tool to increase overall health, vitality, and resistance to disease.

Description

Origins

Detoxification methods of healing have been used for thousands of years. **Fasting** is one of the oldest therapeutic practices in medicine. Hippocrates, the ancient Greek known as the "Father of Western medicine," recommended fasting as a means for improving health. **Ayurvedic medicine**, a traditional healing system that has developed over thousands of years, utilizes detoxification methods to treat many chronic conditions and to prevent illness.

Detoxification treatment has become one of the cornerstones of alternative medicine. Conventional medicine notes that environmental factors can play a significant role in many illnesses. Environmental medicine is a field that studies exactly how those environmental factors influence disease. Conditions such as

WWW.BOOKBAZ.IR

asthma, cancer, chronic fatigue syndrome, **multiple chemical sensitivity**, and many others are strongly influenced by exposure to toxic or allergenic substances in the environment. The U.S. Centers for Disease Control estimate that over 80% of all illnesses have environmental and lifestyle causes.

Detoxification has also become a prominent treatment as people have become more aware of environmental pollution. It is estimated that one in every four Americans has some level of **heavy metal poisoning**. Heavy metals, such as lead, mercury, cadmium, and arsenic, are by-products of industry. Synthetic agriculture chemicals, many of which are known to cause health problems, are also found in food, air, and water. American agriculture uses nearly 10 lb (4.5 kg) of pesticides per person on the food supply each year. These toxins have become almost unavoidable. Pesticides that are used only on crops in the southern United States have been found in the tissue of animals in the far north of Canada. DDT, a cancer-causing insecticide that has been banned for decades, is still regularly found in the fatty tissue of animals, birds, and fish, even in extremely remote regions such as the North Pole.

The problem of toxins in the environment is compounded because humans are at the top of the food chain and are more likely to be exposed to an accumulation of toxic substances in the food supply. For instance, pesticides and herbicides are sprayed on grains that are then fed to farm animals. Toxic substances are stored in the fatty tissue of those animals. In addition, those animals are often injected with synthetic hormones, **antibiotics**, and other chemicals. When people eat meat products, they are exposed to the full range of chemicals and additives used along the entire agricultural chain. Detoxification specialists call this build up of toxins *bioaccumulation*. They assert that the bioaccumulation of toxic substances over time is responsible for many physical and mental disorders, especially ones that are increasing rapidly (like asthma, cancer, and mental illness). As a result, detoxification therapies are increasing in importance and popularity.

Toxins in the body include heavy metals and various chemicals such as pesticides, pollutants, and food additives. Drugs and alcohol have toxic effects in the body. Toxins are produced as normal by-products in the intestines by the bacteria that break down food. The digestion of protein also creates toxic by-products in the body.

The body has natural methods of detoxification. Individual cells get detoxified in the lymph and circulatory system. The liver is the principle organ of detoxification, assisted by the kidneys and intestines. Toxins can be excreted from the body by the kidneys, bowels, skin, and lungs. Detoxification treatments become necessary when the body's natural detoxification systems become overwhelmed. This can be caused by long-term effects of improper diet, **stress**, overeating, sedentary lifestyles, illness, and poor health habits in general. When a build up of toxic substances in the body creates illness, it's called toxemia. Some people's digestive tracts become unable to digest food properly, due to years of overeating and **diets** that are high in fat and processed foods and low in fiber (the average American diet). When this happens, food cannot pass through the digestive tract efficiently. Instead of being digested properly or eliminated from the bowel, food can literally rot inside the digestive tract and produce toxic by-products. This state is known as toxic colon syndrome or intestinal toxemia.

Detoxification therapies try to activate and assist the body's own detoxification processes. They also try to eliminate additional exposure to toxins and strengthen the body and immune system so that toxic imbalances will not occur in the future.

Testing for toxic substances

Detoxification specialists use a variety of tests to determine the causes contributing to toxic conditions. These causes include infections, allergies, addictions, toxic chemicals, and digestive and organ dysfunction. Blood, urine, stool, and hair analyses, as well as **allergy tests**, are used to measure a variety of bodily functions that may indicate problems. Detoxification therapists usually have access to laboratories that specialize in sophisticated diagnostic tests for toxic conditions.

People who have toxemia are often susceptible to infection because their immune systems are weakened. Infections can be caused by parasites, bacteria, viruses, and a common yeast. Therapists will screen patients for underlying infections that may be contributing to illness.

Liver function is studied closely with blood and urine tests because the liver is the principle organ in the body responsible for removing toxic compounds. When the liver detoxifies a substance from the body, it does so in two phases. Tests are performed that indicate where problems may be occurring in these phases, which may point to specific types of toxins. Blood and urine tests can also be completed that

screen for toxic chemicals such as PCBs (environmental poisons), formaldehyde (a common preservative), pesticides, and heavy metals. Another useful blood test is a test for zinc deficiency, which may reveal heavy metal **poisoning**. Hair analysis is used to test for heavy metal levels in the body. Blood and urine tests check immune system activity, and hormone levels can also indicate specific toxic compounds. A 24-hour urine analysis, where samples are taken around the clock, allows therapists to determine the efficiency of the digestive tract and kidneys. Together with stool analysis, these tests may indicate toxic bowel syndrome and digestive system disorders. Certain blood and urine tests may point to nutritional deficiencies and proper recovery diets can be designed for patients as well.

Detoxification therapists may also perform extensive allergy and hypersensitivity tests. Intradermal (between layers of the skin) and sublingual (under the tongue) allergy tests are used to determine a patient's sensitivity to a variety of common substances, including formaldehyde, auto exhaust, perfume, tobacco, chlorine, jet fuel, and other chemicals.

Food allergies require additional tests because these allergies often cause reactions that are delayed for several days after the food is eaten. The RAST (radioallergosorbent test) is a blood test that determines the level of antibodies (immunoglobulins) in the blood after specific foods are eaten. The cytotoxic test is a blood test that determines if certain substances affect blood cells, including foods and chemicals. The ELISA-ACT (enzyme-linked immunoserological assay activated cell test) is considered to be one of the most accurate tests for allergies and hypersensitivity to foods, chemicals, and other agents. Other tests for food allergies are the elimination and rotation diets, in which foods are systematically evaluated to determine the ones that are causing problems.

Detoxification therapists usually interview and counsel patients closely to determine and correct lifestyle, occupational, psychological, and emotional factors that may also be contributing to illness.

Detoxification therapies

Detoxification therapists use a variety of healing techniques after a diagnosis is made. The first step is to eliminate a patient's exposure to all toxic or allergenic substances. These include heavy metals, chemicals, radiation (from x rays, power lines, cell phones, computer screens, and microwaves), smog, polluted water, foods, drugs, **caffeine**, alcohol, perfume, excess noise, and stress. If **mercury poisoning** has been determined, the patient will be advised to have mercury fillings from the teeth removed, preferably by a holistic dentist.

Specific treatments are used to stimulate and assist the body's detoxification process. Dietary change is immediately enacted, eliminating allergic and unhealthy foods, and emphasizing foods that assist detoxification and support healing. **Detoxification diets** are generally low in fat, high in fiber, and vegetarian with a raw food emphasis. Processed foods, alcohol, and caffeine are avoided. **Nutritional supplements** such as **vitamins**, **minerals**, **antioxidants**, amino acids, and essential fatty acids are often prescribed. Spirulina is a sea algae that is frequently given to assist in eliminating heavy metals. Lipotropic agents are certain vitamins and nutrients that promote the flow of bile and fat from the liver.

Many herbal supplements are used in detoxification therapies as well. Milk thistle extract, called silymarin, is one of the more potent herbs for detoxifying the liver. Naturopathy, Ayurvedic medicine, and **traditional Chinese medicine** (TCM) recommend numerous herbal formulas for detoxification and immune strengthening. If infections or parasites have been found, these are treated with herbal formulas and, in difficult cases, antibiotics.

For toxic bowel syndrome and digestive tract disorders, herbal **laxatives** and high fiber foods such as psyllium seeds may be given to cleanse the digestive tract and promote elimination. Colonics are used to cleanse the lower intestines. Digestive enzymes are prescribed to improve digestion, and acidophilus and other friendly bacteria are reintroduced into the system with nutritional supplements.

Fasting is another major therapy in detoxification. Fasting is one of the quickest ways to promote the elimination of stored toxins in the body and to prompt the healing process. People with severe toxic conditions are supervised closely during fasting because the number of toxins in the body temporarily increases as they are being released.

Chelation therapy is used by detoxification specialists to rid the body of heavy metals. Chelates are particular substances that bind to heavy metals and speed their elimination. Homeopathic remedies have also been shown to be effective for removing heavy metals.

Sweating therapies can also detoxify the body because the skin is a major organ of elimination.

WWW.BOOKBAZ.IR

KEY TERMS

Allergen—A foreign substance, such as mites in house dust or animal dander, that when inhaled causes the airways to narrow and produces symptoms of asthma.

Antibody—A protein, also called immunoglobulin, produced by immune system cells to remove antigens (the foreign substances that trigger the immune response).

Fibromyalgia—A condition of debilitating pain, among other symptoms, in the muscles and the myofascia (the thin connective tissue that surrounds muscles, bones, and organs).

Hypersensitivity—The state where even a tiny amount of allergen can cause severe allergic reactions.

Multiple chemical sensitivity—A condition characterized by severe and crippling allergic reactions to commonly used substances, particularly chemicals. Also called environmental illness.

Sweating helps release those toxins that are stored in the subcutaneous (under the skin) fat cells. Saunas, **therapeutic baths**, and **exercise** are some of these treatments. Body therapies may also be prescribed, including **massage therapy**, **acupressure**, **shiatsu**, manual lymph drainage, and **polarity therapy**. These body therapies seek to improve circulatory and structural problems, reduce stress, and promote healing responses in the body. Mind/body therapies such as **psychotherapy**, counseling, and stress management techniques may be used to heal the psychological components of illness and to help patients overcome their negative patterns contributing to illness.

Practitioners and treatment costs

The costs of detoxification therapies can vary widely, depending on the number of tests and treatments required. Detoxification treatments can be lengthy and involved since illnesses associated with toxic conditions usually develop over many years and may not clear up quickly. Detoxification treatments may be lengthy because they often strive for the holistic healing of the body, mind, and emotions.

Practitioners may be conventionally trained medical doctors with specialties in environmental medicine or interests in alternative treatment. The majority of detoxification therapists are alternative practitioners, such as naturopaths, homeopaths, ayurvedic doctors, or traditional Chinese doctors. Insurance coverage varies, depending on the practitioner and the treatment involved. Consumers should review their individual insurance policies regarding treatment coverage.

Preparations

Patients can assist diagnosis and treatment by keeping detailed diaries of their activities, symptoms, and contact with environmental factors that may be affecting their health. Reducing exposure to environmental toxins and making immediate dietary and lifestyle changes may speed the detoxification process.

Side effects

During the detoxification process, patients may experience side effects of fatigue, malaise, aches and pains, emotional duress, **acne**, headaches, allergies, and symptoms of colds and flu. Detoxification specialists claim that these negative side effects are part of the healing process. These reactions are sometimes called *healing crises*, which are caused by temporarily increased levels of toxins in the body due to elimination and cleansing.

Research and general acceptance

Although environmental medicine is gaining more respect within conventional medicine, detoxification treatment is scarcely mentioned by the medical establishment. The research that exists on detoxification is largely testimonial, consisting of individual personal accounts of healing without statistics or controlled scientific experiments. In the alternative medical community, detoxification is an essential and widely accepted treatment for many illnesses and chronic conditions.

Douglas Dupler, MA

Detoxification diets

Definition

Detoxification diets, or detox diets for short, are a group of short-term diets intended to release accumulated toxins and waste products from the body. They are based on a theory of digestion and elimination usually associated with naturopathy, an alternative medical system that emphasizes the role of **nutrition** in restoring or improving the body's own self-healing properties. In general, detox diets emphasize the following:

- Minimal intake of chemicals on or in food by choosing organic or non-processed foods
- Increased intake of fruits, vegetables, and other foods thought to aid the process of detoxification
- Increased intake of foods and fluids that speed up the processes of urination and defecation

Detoxification diets can be categorized into several subgroups: raw food diets, which are based on the premise that uncooked foods prevent the accumulation of toxins in the digestive system; mono diets, in which the dieter consumes only one or two foods (sometimes in liquid form only) for a period of 10–14 days; juice **fasting**, in which the dieter consumes large quantities of fruit and vegetable juices along with water and herbal teas for one to three days; and vegetarian or semi-vegetarian detox diets, which allow the dieter some variety of cooked whole grains, steamed vegetables, fresh fruit, and small amounts of protein foods as well as several glasses of water and herbal teas each day.

Origins

Detoxification diets as a general practice can be traced back for over 5,500 years to an annual ritual of bodily and spiritual preparation known as *pancha karma*, which is part of the practice of **Ayurvedic medicine** in India. Ayurveda is a traditional system of health care that dates back to about 3500 BC; its name is Sanskrit for "science of long life." Pancha karma is undergone for disease prevention, which in Ayurvedic practice requires spiritual renewal and the breaking of negative emotional patterns as well as physical purification. It has three phases: a preparation phase, in which the person eliminates sweets, caffeinated drinks, and processed foods from the diet, as well as spending more time in **meditation** and taking walks in natural surroundings; the cleansing phase, which includes bloodletting, emesis (forced **vomiting**), nasal cleansing, and the use of **enemas** and **laxatives** as well as a very restricted diet of grains and vegetables; and a rejuvenation phase, in which solid foods are gradually reintroduced to the diet. Practitioners of Ayurveda in Canada and the United States generally omit vomiting and bloodletting in the second phase of pancha karma.

In Europe and North America the most important factor in the popularity of detoxification diets is naturopathy, an alternative approach to health care developed out of the natural healing movement in Germany and North America in the late nineteenth century. Naturopathy is closely connected with **vegetarianism**, particularly its raw-food offshoot. Naturopaths of the twenty-first century use a variety of techniques in treating patients, including **hydrotherapy**, spinal manipulation, and **physical therapy** as well as nutrition and dietary advice. There has been a revival of interest in naturopathy in the United States since the 1980s.

Naturopaths frequently recommend detoxification diets as a way of ridding the body of various toxins that they identify as coming from several sources:

- Heavy metals. These include such substances as cadmium, arsenic, nickel, aluminum, chromium, mercury, vanadium, strontium, antimony, cobalt, and lead, which are used in various manufacturing processes and some medical procedures as well as being present in batteries, electronic equipment, coins, cookware, food containers, and other common household items.
- Toxic chemicals taken directly into the digestive tract through alcoholic beverages, pesticide residues on supermarket produce, additives in processed foods, or drugs of abuse; or taken into the respiratory tract through breathing household solvents (nail polish remover, spot or stain removers containing benzene, etc.).
- Toxins in the digestive tract produced by yeast and other microorganisms. Ridding the body of this

WWW.BOOKBAZ.IR

group of toxins is frequently cited as a reason for combining laxatives or enemas with detoxification diets. Mainstream physicians dispute the notion that normal digestion produces toxic substances in the colon that must be removed by a laxative or enema.

- Ammonia, urea, and other breakdown products of protein metabolism. Naturopaths often recommend a vegetarian lifestyle as well as periodic intensive detoxification practices in order to minimize the production of these byproducts of meat and dairy products consumption.

A third factor that has contributed to interest in detox diets in the 1990s and early 2000s is the environmental movement. Some people who are concerned about the impact on the environment of raising animals for food use detox diets as a transition into a long-term vegetarian or vegan lifestyle. In addition, growing awareness of the effects of exposure to industrial chemicals, pesticides, secondhand tobacco smoke, and other contaminants in the home environment as well as the workplace has led many people to consider detoxification diets as a preventive health practice to lower their risk of arthritis and other degenerative diseases.

Description

Practitioners of alternative medicine generally recommend the warmer months as the best time of year for a detox diet, although some dieters prefer January in order to counteract the effects of overindulgence in food and drink during the holidays. Many people suggest beginning a detox diet on the weekend or scheduling time off from work in order to allow time for extra rest if needed. Detox diets are usually used only once or twice a year.

Many detoxification diet books include a questionnaire or symptom checklist to help readers evaluate whether they need detoxification. The following list is typical; more than four "yes" answers indicates the individual could benefit from a detox diet:

- Do you have only one bowel movement per day, or only one every other day?
- Do you take prescription, recreational, or over-the-counter drugs?
- Do you eat meat more than twice a week?
- Do you eat fast foods or processed foods?
- Do you smoke, or are you exposed to secondhand smoke?
- Do you have any skin problems or digestive gas and bloating?
- Do you drink alcohol?
- Do you live in a major city?
- Do you drink tap water, coffee, or soda?
- Do you feel tired, sleep poorly, or have low energy?

Individuals considering a detox diet should prepare by cutting down gradually on caffeinated beverages a week to 10 days before the diet, as sudden elimination of these drinks often causes headaches. Dieters should also reduce their intake of sugary foods, chocolate, alcohol, dairy products, foods high in fat, foods containing wheat or yeast, and grains containing gluten (an elastic protein found in barley and rye). Recommended foods for detox diets (except the mono diets) include fresh organic fruits and vegetables; rice (both brown and basmati rice), rice cakes, and rice pasta; other grains such as millet, quinoa, and buckwheat; beans, lentils, and dried green or yellow peas; unsalted nuts; seeds; olive oil; and herbal teas. The dieter should plan to drink at least eight glasses of filtered or other non-tap water per day on a detox diet.

At the end of a detox diet, the dieter should return gradually to a full diet, perhaps vegetable soup or steamed vegetables the first day. They should not add fruits or vegetables until the second or third day.

Raw food diets

Raw food detox diets consist of foods that have not been heated above 92–118°F (33–48°C). These diets are based on the belief that raw foods have higher nutrient value and contain enzymes that assist digestion, allowing the other enzymes in the body to regulate other biological processes. Raw foodists also believe raw foods prevent **obesity** by lowering excessive food consumption, and their high fiber content helps detoxify the body by speeding up digestion and elimination.

Juice fasting

In a juice fast, the dieter is instructed to drink between 32 and 64 oz of fruit or vegetable juice per day, in addition to six glasses of warm filtered water. Although some modified juice fasts allow a small quantity of steamed vegetables, most are short-term liquid diets. Some therapists recommend one or more cups of herbal tea each day in addition to the juice and water. The juice must be fresh, obtained from organic fruits and vegetables processed through a juicer or juice extractor. Prepackaged juices cannot be used for a juice fast because they have been

pasteurized. In addition, fresh juice must be consumed within a half hour of extraction; it cannot be refrigerated.

Mono diets

Mono diets are detox diets in which the dieter consumes only one food, usually apples, grapes, or some other fruit or vegetable, or one liquid, for a period of 10 to 14 days. The oldest mono diet is the so-called Miracle Grape Cure, attributed to Johanna Brandt, a woman from South Africa who claimed that eating grapes cured her of **stomach cancer**. In a book she published in 1928, Brandt stated that she alternated 12 hours of drinking only natural (unchlorinated) water with 12 hours of eating only purple grapes or drinking grape juice made from purple grapes. Recent modifications of this diet recommend following Brandt's plan to the letter for five weeks, followed by one week of a raw-food vegetarian diet.

The best-known mono diet is variously known as the Master Cleanser, lemonade diet, or maple syrup diet. Stanley Burroughs is generally credited with inventing this diet in 1941, although he did not publish it in book form until 1976. His book, which is only about 50 pages long, is still in print even though Burroughs died in 1991. The Master Cleanser involves drinking a mixture of lemon juice, cayenne pepper, and grade B maple syrup for a period of 10 to 14 days. The lemon/maple syrup drink is then followed by drinking a "saltwater flush," which is supposed to purge toxins from the stomach and bowels. This diet was popularized in the early 2000s by a book by Peter Glickman titled *Lose Weight, Have More Energy and Be Happier in 10 Days*, which is a modernization of Burrough's regimen.

Vegetarian or semivegetarian diets

Less stringent detox diets that allow some protein foods have been published; a typical example is the following diet plan for a week-long detox regimen by Elson Haas. Haas begins with general guidelines for the dieter:

- Eat slowly and chew the food well.
- Relax for a few minutes before and after each meal.
- Eat in a comfortable sitting position.
- Drink only herbal teas (peppermint, chamomile, or pau d'arco) after dinner.

The daily diet plan:

- Morning: two glasses of filtered or spring water, one glass with half a lemon squeezed into it.
- Breakfast: One piece of fresh fruit at room temperature, followed 15 to 30 minutes later by a bowl of cooked whole grains (millet, buckwheat, quinoa, brown rice, or amaranth), flavored with 2 tbsp of fruit juice.
- Lunch: One or two medium bowls of steamed vegetables, using a variety of root vegetables, leafy vegetables, asparagus, cabbage, kale, or others. A maximum of 3 tsp daily of a mixture of butter and canola or olive oil can be used for seasoning.
- Dinner: Same as lunch.
- Midmorning and midafternoon: One or two cups of vegetable water saved from the steamed vegetables, with a little sea salt or kelp added.
- A small portion (3–4 oz) of a protein food (fish, organic chicken, lentils, black beans, or garbanzo beans) may be eaten midafternoon if the dieter feels weak or extremely hungry.

Supplemental recommendations

An important part of many detoxification diets is the use of laxatives or enemas to cleanse the lower digestive tract. The removal of wastes is considered essential to prevent toxins in the intestines from being reabsorbed into the bloodstream. Some alternative therapists recommend mixtures of slippery elm or other herbs to cleanse the colon; others prefer saltwater laxatives, enemas, or colonics for cleansing the bowel. A colonic is a procedure in which a large amount of water, sometimes as much as 20 gal (76 L), is infused into the colon through the rectum a few pints at a time. It differs from an enema in that much more fluid is used; and a colonic is infused into the colon, whereas an enema infuses water or a cleansing solution into the rectum only. Mainstream physicians do not recommend colonics on the grounds that they are unnecessary, based on a nineteenth-century misunderstanding of the process of digestion, and very often uncomfortable for the patient. In some cases they pose serious risks to health.

Some therapists recommend the use of such dietary supplements as multivitamins, vitamin C, choline and methionine, milk thistle, or a laxative tea known as Smooth Move during a detox diet. These supplements are supposed to aid liver function and decrease such side effects of detox diets as headaches and nausea.

Many advocates of detox diets suggest the use of meditation, affirmations, **yoga**, and other spiritual practices in order to improve the mental and emotional well-being. Others recommend undertaking the

WWW.BOOKBAZ.IR

detox diet at a health spa, where such services as **massage therapy**, sauna baths, and whirlpool therapy or other forms of hydrotherapy are available.

Function

The primary function of detoxification diets is physical purification—removal of toxic substances from the body including the skin and respiratory system as well as the digestive tract—in order to raise energy levels; relieve such minor health complaints as poor skin, **bad breath**, or headaches; and improve the body's ability to heal from various diseases. These diets are not primarily intended as weight reduction regimens.

Spiritual or religious practice

Some people undertake detoxification diets as part of a general religious or spiritual retreat. The first stage of Ayurvedic pancha karma includes extra time given to meditation and nature walks as well as gradual exclusion of stimulants and solid foods from the diet. Many people also report relief from **insomnia** or other symptoms of emotional **stress** as a side benefit of detoxification diets.

Treatment of specific illnesses

Detoxification diets are sometimes recommended for the treatment of specific diseases and disorders, most commonly arthritis, **autoimmune disorders**, and depression, but they have also been claimed to be an effective treatment for severe infections (including **AIDS**) and cancer. However, there is insufficient evidence to support such claims.

Benefits

Claimed benefits of detox diets include higher energy levels, increased mental clarity and ability to concentrate, clearer skin, improved digestion, and more restful sleep. Many of these improvements may simply be due to better hydration as such diets encourage high fluid intake. Some people also lose weight on detox diets, but emphasize that weight reduction should never be the primary purpose of following one of these regimens.

Precautions

In general, anyone considering a detoxification diet should consult a health professional beforehand. Some serious diseases, including cancer, may have minor symptoms at onset, including headaches, **low back pain**, and **fatigue**. These symptoms can easily be misattributed to stress or poor eating habits. Some therapists recommend requesting blood, urine, stool, and **liver function tests** from a physician before undergoing a detoxification diet.

Individuals who should not undertake a detoxification diet are:

- Pregnant or lactating women.
- Children.
- People with diabetes, hypothyroidism, heart disease, anorexia or bulimia nervosa, kidney or liver disease, stomach ulcers, impaired immune function, epilepsy, cancer, terminal illness, active infections, or ulcerative colitis.
- People who are underweight.
- People with alcohol or drug addictions.
- People who have recently undergone surgery or treatment for severe burns.

Prescription medications should be taken as usual during a detoxification diet. The dieter should not discontinue medications or reduce dosages without consulting a physician.

Anyone on a detoxification diet who feels faint or dizzy, develops an abnormal heart rhythm, feels nauseated or vomits, or has signs of low blood pressure, should discontinue the fast and consult their doctor at once.

Detox diets may encourage yo-yo dieting, which is detrimental to health. They should not be undertaken more than three times a year without medical supervision.

Risks

The major risks to health from detoxification diets include metabolic crises in patients with undiagnosed diabetes; flare-ups or worsening of stomach **ulcers**; **dizziness** or **fainting** due to sudden lowering of blood pressure; **diarrhea** that may result in **dehydration** and an imbalance of electrolytes in the body; and protein or **calcium** deficiencies from unsupervised long-term juice fasts. Some people develop **dental erosion** from raw-food detoxification diets.

Other side effects reported include headaches (often caused by sudden withdrawal from **caffeine**), fatigue, **constipation** (from extra fiber combined with inadequate water intake), **acne**, irritability, **dysmenorrhea** (painful periods) in women, and intense hunger.

Raw-food detoxification diets increase the risk of contracting parasites or other foodborne illnesses caused by organisms normally destroyed in cooking

or pasteurization. In addition, some raw vegetables, such as rhubarb leaves and stalks, buckwheat greens, kidney beans, kidney bean sprouts, and raw potatoes that have turned green are toxic, particularly if consumed in large quantities.

People on detoxification diets who undergo colonics are at risk of contracting an infection from improperly sterilized colonic equipment; of serious illness or death from electrolyte imbalances in the blood; or of serious illness or death resulting from perforation of the intestinal wall by improperly inserted equipment. Colonics can also worsen the symptoms of ulcerative **colitis**.

Research and general acceptance

Detoxification diets are generally dismissed as fads by such professional nutritionists' organizations as the American Dietetic Association (ADA) and other mainstream medical groups. Most physicians point out that the human body is a remarkably efficient organism that can rid itself of toxins through normal digestion, respiration, and excretion without elaborate diets or the assistance of enemas and laxatives. In addition, some fruits and vegetables may contain more toxins than meat, fish, and other protein-rich foods usually condemned by proponents of detoxification diets. Lastly, many physicians object to the naturopathic view of the digestive tract as a source of illness or toxicity.

Deviated septum

Definition

The nasal septum is a thin structure, separating the two sides of the nose. If it is not in the middle of the nose, then it is deviated.

Description

The nasal septum is composed of two parts. Toward the back of the head the nasal septum is rigid bone, but further forward the bone becomes cartilage. With one finger in each nostril this cartilage can easily be bent back and forth. If the nasal septum

WWW.BOOKBAZ.IR

A close-up of person with a deviated septum. *(Custom Medical Stock Photo, Inc.)*

is sufficiently displaced to one side, it will impede the flow of air and mucus through the nose. This condition, called a deviated septum, can cause symptoms and disease.

Causes and symptoms

A deviated septum can be a simple variation in normal structure or the result of a broken nose. Any narrowing of the nasal passageway that it causes will threaten the drainage of secretions from the sinuses, which must pass through the nose. It is a general rule of medicine that when flow is obstructed, whether it is mucus from the sinuses or bile from the gall bladder, infection results. People with **allergic rhinitis** (hay **fever**) are at greater risk of obstruction because their nasal passageways are already narrowed by the swollen membranes lining them. The result is **sinusitis**, which can be acute and severe or chronic and lingering.

Diagnosis

It is easy to see that a septum is deviated. It is more difficult to determine if that deviation needs correction. It is common for a patient to complain that he/she can breathe through only one nostril. Then the diagnosis is easy. A deviated septum may also contribute to **snoring**, **sleep apnea**, and other breathing disorders.

Treatment

The definitive treatment is surgical repositioning of the septum, accomplished by breaking it loose and fixing it in a proper place while it heals. **Decongestants** like pseudoephedrine or phenylpropanolamine will shrink the membranes and thereby enlarge the passages. **Antihistamines**, nasal cortisone spray, and other allergy treatments may also be temporarily beneficial.

Alternatives

As a palliative, saline drops and sprays are very helpful in loosening mucus in the obstructed side and preventing drying in the other side, where all the air blows. Hot peppers, such as jalapenos, can produce enough tears and discharge to flush out a stopped-up nose. An even more effective treatment is called a nasal lavage, often done using a small pot with a spout. Saline solution is poured into one nostril and allowed to flow out the other nostril. Then, the process is repeated in reverse. These therapies are all useful to take care of symptoms, but do not correct the problem. Nasospecific, a procedure where a deflated balloon is inserted in the nostril and inflated to a large enough degree to adjust the septal deviation, can be an alternative to surgery. A trained practitioner in the nasospecific procedure is necessary.

Prognosis

Surgical repair is curative and carries little risk. Chronic infection can be painful and lead to complications until it is resolved. If there is continued obstruction, the infection will very likely return.

Prevention

Avoidance of virus colds, airborne dusts, air pollution, and known allergens will minimize the irritation and swelling of the membranes lining the nasal passages.

KEY TERMS

Allergen—Any substance that irritates people sensitive (allergic) to it.

Allergic rhinitis—Swelling and inflammation of the nasal membranes caused by sensitivity to airborne matter like pollen or cat hair.

Saline—A salt solution in water. Normal saline has the same salt concentration as the body, 0.9%.

Sinuses—The nasal sinuses, air-filled cavities surrounding the eyes and nose, like the nose itself are lined with mucus-producing membranes. They provide cleansing to the nose, resonance to the voice, and structure to the face.

Sinusitis—Infection of the sinuses.

Sleep apnea—A condition in which breathing is temporarily interrupted during sleep. It leads to high blood pressure, sleepiness, and a variety of other problems.

Diabetes insipidus

Definition

Diabetes insipidus (DI) is a disorder that causes the patient to produce tremendous quantities of urine. The massively increased urine output is usually accompanied by intense thirst.

Description

The balance of fluid within the body is maintained through a number of mechanisms. One important chemical involved in fluid balance is called antidiuretic hormone (ADH). ADH is produced by the pituitary, a small gland located at the base of the brain. In a healthy person and under normal conditions, ADH is continuously released. ADH influences the amount of fluid that the kidneys reabsorb into the circulatory system and the amount of fluid that the kidneys pass out of the body in the form of urine.

Production of ADH is regulated by the osmolality of the circulating blood. Osmolality refers to the concentration of dissolved chemicals (such as **sodium**, potassium, and chloride; together called solute) circulating in the fluid base of the blood (plasma). When there is very little fluid compared to the concentration of solute, the pituitary will increase ADH production. This tells the kidneys to retain more water and to decrease the amount of urine produced. As fluid is retained, the concentration of solute will normalize. At other times, when the fluid content of the blood is high in comparison to the concentration of solute, ADH production will decrease. The kidneys are then free to pass an increased amount of fluid out of the body in the urine. Again, this will allow the plasma osmolality to return to normal.

Diabetes insipidus occurs when either the amount of ADH produced by the pituitary is below normal (central DI), or the kidneys' ability to respond to ADH is defective (nephrogenic DI). In either case, a person with DI will pass extraordinarily large quantities of urine, sometimes reaching 10 or more liters each day. At the same time, the patient's blood will be very highly concentrated, with low fluid volume and high concentrations of solute.

DI occurs on average when a person is about 24 years old, and occurs more frequently in males than in females.

Causes and symptoms

DI may run in families. The cause of this type of DI is unknown. Other times, central DI can be caused by:

- an injury to the head
- brain surgery
- cancers that have spread to the pituitary gland (most commonly occurring with breast cancer)
- sarcoidosis (or other related disorders), causing destruction of the pituitary gland
- any condition or illness that causes decreased oxygen delivery to the brain
- the use of certain medications that decrease ADH production (like the antiseizure drug phenytoin)
- the excessive use of alcohol

WWW.BOOKBAZ.IR

Central DI may also occur in women who are pregnant or have just given birth, and in patients with **AIDS** who have suffered certain types of brain infections. Nephrogenic DI sometimes occurs in patients who are taking the medication lithium, patients who have high levels of blood **calcium**, and patients who are pregnant.

DI is easily confused with an entirely unrelated disorder, psychogenic polydipsia. Polydipsia refers to drinking large amounts of water. Psychogenic polydipsia is a psychiatric problem that makes a person drink huge quantities of water uncontrollably.

Symptoms of DI include extreme thirst and the production of tremendous quantities of urine. Patients with DI typically drink huge amounts of water, and usually report a specific craving for cold water. When the amount of water passed in the urine exceeds the patient's ability to drink ample replacement water, the patient may begin to experience symptoms of **dehydration**. These symptoms include weakness, **fatigue**, **fever**, low blood pressure, increased heart rate, **dizziness**, and confusion. If left untreated, the patient could lapse into unconsciousness and die.

Diagnosis

Diagnosis should be suspected in any patient with sudden increased thirst and urination. Laboratory examination of urine will reveal very dilute urine, made up mostly of water with no solute. Examination of the blood will reveal very concentrated blood, high in solute and low in fluid volume.

A water deprivation test may be performed. This test requires a patient to stop all fluid intake. The patient is weighed just before the test begins, and urine is collected and examined hourly. The test is stopped when:

- the patient has lost more than 5% of his or her original body weight
- the patient has reached certain limits of low blood pressure and increased heart rate
- the urine is no longer changing significantly from one sample to the next in terms of solute concentration

The next step of the test involves injecting a synthetic form of ADH, with one last urine sample examined 60 minutes later. Comparing plasma and urine osmolality allows the doctor to diagnose either central DI, nephrogenic DI, partial DI, or psychogenic polydipsia.

KEY TERMS

Concentration—Refers to the amount of solute present in a solution, compared to the total amount of solvent.

Dilute—A solution that has comparatively more fluid in it, relative to the quantity of solute.

Osmolality—A measure of the solute-to-solvent concentration of a solution.

Solute—Solid substances that are dissolved in liquid in order to make a solution.

Treatment

A number of medications can be given to decrease the quantity of fluid passed out into the urine. These include vasoprassin (Pitressin) injected and desmopressin acetate (DDAVP) inhaled through the nose, injected under the skin, or taken orally. Other medications that may be given include some antidiuretic drugs (chlorpropamide, clofibrate, carbamazepine). Patients with nephrogenic DI, however, will also require special **diets** that restrict the amount of solute taken in. These patients are also treated with a type of medication called a thiazide diuretic.

Prognosis

Uncomplicated diabetes insipidus is controllable with adequate intake of water and most patients can lead normal lives.

Diabetes mellitus

Definition

Diabetes mellitus is a condition in which the pancreas no longer produces enough insulin or cells stop responding to the insulin that is produced, so that glucose in the blood cannot be absorbed into the cells of the body. Symptoms include frequent urination, lethargy, excessive thirst, and hunger. Treatment can include changes in diet, lifestyle habits, oral medications, and daily injections of insulin, especially with type 1 diabetes.

Insulin Preparations

Type of Insulin	Brand Name	Generic Name	Onset	Peak	Duration
Rapid-acting	NovoLog	Insulin aspart	15 minutes	30 to 90 minutes	3 to 5 hours
	Apidra	Insulin glulisine	15 minutes	30 to 90 minutes	3 to 5 hours
	Humalog	Insulin lispro	15 minutes	30 to 90 minutes	3 to 5 hours
Short-acting	Humulin R	Regular (R)	30 to 60 minutes	2 to 4 hours	5 to 8 hours
	Novolin R				
Intermediate-acting	Humulin N	NPH (N)	1 to 3 hours	8 hours	12 to 16 hours
	Novolin N				
Long-acting	Levemir	Insulin detemir	1 hour	Peakless	20 to 26 hours
	Lantus	Insulin glargine			
Pre-mixed NPH (intermediate-acting) and regular (short-acting)	Humulin 70/30 Novolin 70/30	70% NPH and 30% regular	30 to 60 minutes	Varies	10 to 16 hours
	Humulin 50/50	50% NPH and 50% regular	30 to 60 minutes	Varies	10 to 16 hours
Pre-mixed insulin lispro protamine suspension (intermediate-acting) and insulin lispro (rapid-acting	Humalog Mix 75/25	75% insulin lispro protamine and 25% insulin lispro	10 to 15 minutes	Varies	10 to 16 hours
	Humalog Mix 50/50	50% insulin lispro protamine and 50% insulin lispro	10 to 15 minutes	Varies	10 to 16 hours
Pre-mixed insulin aspart protamine suspension (intermediate-acting) and insulin aspart (rapid-acting)	NovoLog Mix 70/30	70% insulin aspart protamine and 30% insulin aspart	5 to 15 minutes	Varies	10 to 16 hours

Man measuring sugar with home blood glucose meter.
(@cpy; bikeriderlondon/Shutterstock.com)

Description

Diabetes mellitus is a chronic disease that causes serious health complications including renal (kidney) failure, **heart disease**, **stroke**, and blindness. Approximately 17 million Americans have diabetes. Unfortunately, as many as one-half are unaware they have it, and rates are expected to continue to increase due to the high prevalence of **obesity** in the United States. Worldwide, the number of people with diabetes is increasing due to population growth, **aging**, urbanization, and an increased prevalence of obesity and physical inactivity.

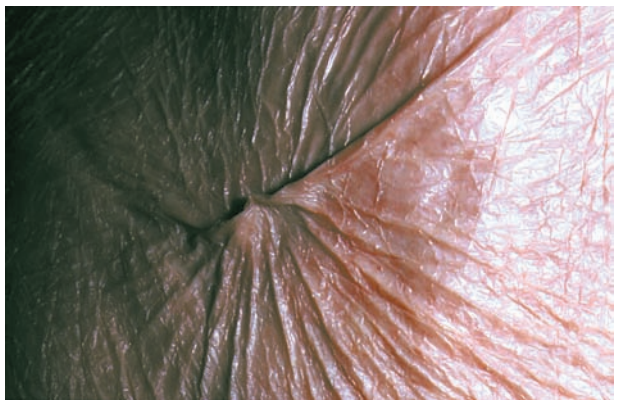
Every cell in the human body needs energy in order to function. The body's primary energy source is glucose, a simple sugar resulting from the digestion of foods containing carbohydrates (sugars and starches). Glucose from the digested food circulates in the blood as a ready energy source for any cells that need it. Insulin is a hormone or chemical produced by cells in the pancreas, an organ located behind the stomach. Insulin binds to a receptor site on the outside of a cell and acts like a key to open a doorway into the cell through which glucose can enter. Some of the glucose can be converted to concentrated energy sources like glycogen or fatty acids and saved for later use. When there is not enough insulin produced or when the doorway no longer recognizes the insulin key, glucose stays in the blood rather entering the cells.

The body will attempt to dilute the high level of glucose in the blood, a condition called hyperglycemia, by drawing water out of the cells and into the bloodstream in an effort to dilute the sugar and excrete it in the urine. It is not unusual for people with undiagnosed diabetes to be constantly thirsty, drink large quantities of water, and urinate frequently as their bodies try to get rid of the extra glucose. This creates high levels of glucose in the urine.

At the same time that the body is trying to get rid of glucose from the blood, the cells are starving for glucose and sending signals to the body to eat more food, thus making patients extremely hungry. To provide energy for the starving cells, the body also tries to convert fats and proteins to glucose. The breakdown of fats and proteins for energy causes acid compounds called ketones to form in the blood. Ketones also will be excreted in the urine. As ketones build up in the blood, a condition called ketoacidosis can occur. This condition can be life threatening if left untreated, leading to **coma** and death.

Type 1 diabetes, sometimes called juvenile diabetes, begins most commonly in childhood or adolescence. In this form of diabetes, the body produces little or no insulin. It is characterized by a sudden onset and occurs more frequently in populations descended from Northern European countries (Finland, Scotland, Scandinavia) than in those from Southern European countries, the Middle East, or Asia. In the United States, approximately three people in 1,000 develop type 1 diabetes. This form is also called insulin-dependent diabetes because people who develop this type need to have daily injections of insulin.

Brittle diabetes is a subgroup of type 1 where patients have frequent and rapid swings of blood sugar levels between hyperglycemia (a condition where there is too much glucose or sugar in the blood) and **hypoglycemia** (a condition where there are abnormally low levels of glucose or sugar in the blood). These patients may require several injections of



Wrinkled, dehydrated skin of a person in a diabetic coma. Untreated diabetes mellitus results in elevated blood glucose levels, causing a variety of symptoms that can culminate in a diabetic coma. *(Dr. P. Marazzi/SPL/Photo Researchers, Inc.)*

different types of insulin during the day to keep the blood sugar level within a fairly normal range.

The more common form of diabetes, type 2, occurs in approximately 3–5% of Americans under 50 years of age, and increases to 10–15% in those over 50. More than 90% of people with diabetes in the United States have type 2. Sometimes called age-onset or adult-onset diabetes, this form of diabetes occurs most often in people who are overweight and who do not **exercise**. Evidence suggests that a 1Êkg/m2 increase in BMI increases the risk of developing new-onset type 2 diabetes by 8%. It is also more common in people of Native American, Hispanic, and African-American descent. People who have migrated to Western cultures from East India, Japan, and Australian Aboriginal cultures also are more likely to develop type 2 diabetes than those who remain in their original countries.

Type 2 is considered a milder form of diabetes because of its slow onset (sometimes developing over the course of several years) and because it usually can be controlled with diet and oral medication. The consequences of uncontrolled and untreated type 2 diabetes, however, are just as serious as those for type 1. This form is also called noninsulin-dependent diabetes, a term that is somewhat misleading. Many people with type 2 diabetes can control the condition with diet and oral medications, however, insulin injections are sometimes necessary if treatment with diet and oral medication is not working.

Another form of diabetes called **gestational diabetes** can develop during **pregnancy** and generally resolves after the baby is delivered. This diabetic condition develops during the second or third trimester of pregnancy in about 2% of pregnancies. In 2004, incidence of gestational diabetes was reported to have increased 35% in 10 years. Children of women with gestational diabetes are more likely to be born prematurely, have hypoglycemia, or have severe **jaundice** at birth. The condition usually is treated by diet, however, insulin injections may be required. These women who have diabetes during pregnancy are at higher risk for developing type 2 diabetes within 5–10 years.

Diabetes also can develop as a result of pancreatic disease, **alcoholism**, **malnutrition**, or other severe illnesses that **stress** the body.

Causes and symptoms

Causes

While the causes of diabetes mellitus are unclear, there seem to be both hereditary (genetic factors passed on in families) and environmental factors involved. Research has shown that some people who develop diabetes have common genetic markers. In type 1 diabetes, the immune system, the body's defense system against infection, is believed to be triggered by a virus or another microorganism that destroys cells in the pancreas that produce insulin. In type 2 diabetes, age, obesity, and family history of diabetes play a role.

In type 2 diabetes, the pancreas may produce enough insulin, however, cells have become resistant to the insulin produced and it may not work as effectively. Symptoms of type 2 diabetes can begin so gradually that a person may not know that he or she has it. Early signs are lethargy, extreme thirst, and frequent urination. Other symptoms may include sudden weight loss, slow wound healing, urinary tract infections, gum disease, or blurred vision. It is not unusual for type 2 diabetes to be detected while a patient is seeing a doctor about another health concern that is actually being caused by the yet undiagnosed diabetes.

Individuals who are at high risk of developing type 2 diabetes mellitus include people who:

- are obese (more than 20% above their ideal body weight)
- have a high waist circumference
- have a relative with diabetes mellitus
- belong to a high-risk ethnic population (African-American, Native American, Hispanic, or Native Hawaiian)

WWW.BOOKBAZ.IR

- have been diagnosed with gestational diabetes or have delivered a baby weighing more than 9 lbs (4 kg)
- have high blood pressure (140/90 mmHg or above)
- have a high density lipoprotein cholesterol level less than or equal to 35 mg/dL and/or a triglyceride level greater than or equal to 250 mg/dL
- have had impaired glucose tolerance or impaired fasting glucose on previous testing

Several common medications can impair the body's use of insulin, causing a condition known as secondary diabetes. These medications include treatments for high blood pressure (furosemide, clonidine, and thiazide **diuretics**), drugs with hormonal activity (**oral contraceptives**, thyroid hormone, progestins, and glucocorticoids), and the anti-inflammation drug indomethacin. Several drugs that are used to treat **mood disorders** (such as **anxiety** and depression) also can impair glucose absorption. These drugs include haloperidol, lithium carbonate, phenothiazines, tricyclic antidepressants, and adrenergic agonists. Other medications that can cause diabetes symptoms include isoniazid, nicotinic acid, cimetidine, and heparin. A 2004 study found that low levels of the essential mineral chromium in the body may be linked to increased risk for diseases associated with **insulin resistance**.

Symptoms

Symptoms of diabetes can develop suddenly (over days or weeks) in previously healthy children or adolescents, or can develop gradually (over several years) in overweight adults over the age of 40. The classic symptoms include feeling tired and sick, frequent urination, excessive thirst, excessive hunger, and weight loss.

Ketoacidosis, a condition due to **starvation** or uncontrolled diabetes, is common in type 1 diabetes. Ketones are acid compounds that form in the blood when the body breaks down fats and proteins. Symptoms include abdominal **pain**, **vomiting**, rapid breathing, extreme lethargy, and drowsiness. Patients with ketoacidosis will also have a sweet breath odor. Left untreated, this condition can lead to coma and death.

With type 2 diabetes, the condition may not become evident until the patient presents for medical treatment for some other condition. A patient may have heart disease, chronic infections of the gums and urinary tract, blurred vision, numbness in the feet and legs, or slow-healing **wounds**. Women may experience genital **itching**.

Diagnosis

Diabetes is suspected based on symptoms. Urine tests and blood tests can be used to confirm a diagnose of diabetes based on the amount of glucose found. Urine tests can also detect ketones and protein that may help diagnose diabetes and assess how well the kidneys are functioning. These tests also can be used to monitor the disease once the patient is on a standardized diet, oral medications, or insulin.

Clinistix and Diastix are paper strips or dipsticks that change color when dipped in urine. The test strip is compared to a chart that shows the amount of glucose in the urine based on the change in color. The level of glucose in the urine lags behind the level of glucose in the blood. Testing the urine with a test stick, paper strip, or tablet that changes color when sugar is present is not as accurate as blood testing, however it can give a fast and simple reading.

Ketones in the urine can be detected using similar types of dipstick tests (Acetest or Ketostix). Ketoacidosis can be a life-threatening situation, so having a quick and simple test to detect ketones can assist in establishing a diagnosis sooner.

Another dipstick test can determine the presence of protein or albumin in the urine. Protein in the urine can indicate problems with kidney function and can be used to track the development of renal failure. A more sensitive test for urine protein uses radioactively tagged chemicals to detect microalbuminuria, small amounts of protein in the urine, that may not show up on dipstick tests.

A blood test can also determine if a patient is diabetic. For a fasting glucose test, blood is drawn from a vein in the patient's arm after a period at least eight hours when the patient has not eaten, usually in the morning before breakfast. The red blood cells are separated from the sample and the amount of glucose is measured in the remaining plasma. A plasma level of 7.8 mmol/L (200 mg/L) or greater can indicate diabetes. The fasting glucose test is usually repeated on another day to confirm the results.

For a postprandial glucose test, blood is taken right after the patient has eaten a meal.

In oral glucose tolerance tests, blood samples are taken from a vein before and after a patient drinks a thick, sweet syrup of glucose and other sugars. In a non-diabetic, the level of glucose in the blood goes up

immediately after the drink and then decreases gradually as insulin is used by the body to metabolize, or absorb, the sugar. In a diabetic, the glucose in the blood goes up and stays high after drinking the sweetened liquid. A plasma glucose level of 11.1 mmol/L (200 mg/dL) or higher at two hours after drinking the syrup and at one other point during the two-hour test period confirms the diagnosis of diabetes.

A diagnosis of diabetes is confirmed if there are symptoms of diabetes and a plasma glucose level of at least 11.1 mmol/L, a fasting plasma glucose level of at least 7.8 mmol/L, or a two-hour plasma glucose level of at least 11.1 mmol/L during an oral glucose tolerance test.

Home blood glucose monitoring kits are available so patients with diabetes can monitor their own levels. A small needle or lancet is used to prick the finger and a drop of blood is collected and analyzed by a monitoring device. Some patients may test their blood glucose levels several times during a day and use this information to adjust their doses of insulin.

Treatment

There is currently no cure for diabetes. The condition, however, can be managed so that patients can live a relatively normal life. Treatment of diabetes focuses on two goals: keeping blood glucose within normal range and preventing the development of long-term complications. Careful monitoring of diet, exercise, and blood glucose levels are as important as the use of insulin or oral medications in preventing complications of diabetes. Each year, the American Diabetes Association updates its standards of care for the management of diabetes. These standards help manage healthcare providers in the most recent recommendations for diagnosis and treatment of the disease.

Diet and moderate exercise are the first treatments implemented in diabetes. For many people with type 2 diabetes, weight loss may be an important goal in helping them to control their diabetes. A well-balanced, nutritious diet provides approximately 50–60% of calories from mostly complex carbohydrates, approximately 10–20% of calories from protein, and less than 30% of calories from fat. The number of calories required by an individual depends on age, weight, and activity level. The calorie intake also needs to be distributed over the course of the entire day so surges of glucose entering the blood system are kept to a minimum.

Keeping track of the number of calories provided by different foods can become complicated, so patients usually are advised to consult a nutritionist or dietitian. An individualized, easy to manage diet plan can be set up for each patient. Both the American Diabetes Association and the Academy of **Nutrition** and Dietetics recommend **diets** based on the use of food exchange lists. Each food exchange contains a known amount of calories in the form of protein, fat, or carbohydrate. A patient's diet plan will consist of a certain number of exchanges from each food category (meat or protein, fruits, breads and starches, vegetables, and fats) to be eaten at meal times and as snacks. Patients have flexibility in choosing which foods they eat as long as they stick with the number of exchanges prescribed.

Oral medications are available to lower blood glucose in people with type 2 diabetes. In 1990, 23.4 million outpatient prescriptions for oral antidiabetic agents were dispensed. By 2001, the number had increased to 91.8 million prescriptions. Oral antidiabetic agents accounted for more than $5 billion dollars in worldwide retail sales per year in the early twenty-first century and were the fastest-growing segment of diabetes drugs.

The drugs first prescribed for type 2 diabetes are in a class of compounds called sulfonylureas and include tolbutamide, tolazamide, acetohexamide, and chlorpropamide. Newer drugs in the same class are now available and include glyburide, glimepiride, and glipizide. How these drugs work is not well understood, however, they seem to stimulate cells of the pancreas to produce more insulin. New medications that are available to treat diabetes include metformin, acarbose, and troglitazone. The choice of medication depends in part on the individual patient profile.

All drugs have side effects that may make them inappropriate for particular patients. Some, for example, may stimulate weight gain or cause stomach irritation, so they may not be the best treatment for someone who is already overweight or who has stomach **ulcers**. Others, like metformin, have been shown to have positive effects such as reduced cardiovascular mortality, but increased risk in other situations. While these medications are an important aspect of treatment for type 2 diabetes, they are not a substitute for a well-planned diet and moderate exercise. Oral medications have not been shown effective for type 1 diabetes, in which the patient produces little or no insulin.

WWW.BOOKBAZ.IR

Constant advances are being made in development of new oral medications for people with diabetes. In 2003, a drug called Metaglip combining glipizide and metformin was approved in a single tablet. Along with diet and exercise, the drug was used as initial therapy for type 2 diabetes. Another drug approved by the U.S. Food and Drug Administration (FDA) combines metformin and rosiglitazone (Avandia), a medication that increases muscle cells' sensitivity to insulin. It is marketed under the name Avandamet. So many new drugs are under development that it is best to stay in touch with a physician for the latest information; physicians can find the best drug, diet, and exercise program to fit an individual patient's need.

Patients with type 1 diabetes need daily injections of insulin to help their bodies use glucose. The amount and type of insulin required depends on the height, weight, age, food intake, and activity level of the individual diabetic patient. Some patients with type 2 diabetes may need to use insulin injections if their diabetes cannot be controlled with diet, exercise, and oral medication. Injections are given subcutaneously, that is, just under the skin, using a small needle and syringe. Injection sites can be anywhere on the body where there is looser skin, including the upper arm, abdomen, or upper thigh.

Purified human insulin is most commonly used, however, insulin from beef and pork sources also are available. Insulin may be given as an injection of a single dose of one type of insulin once a day. Different types of insulin can be mixed and given in one dose or split into two or more doses during a day. Patients who require multiple injections over the course of a day may be able to use an insulin pump that administers small doses of insulin on demand. The small battery-operated pump is worn outside the body and is connected to a needle that is inserted into the abdomen. Pumps can be programmed to inject small doses of insulin at various times during the day, or the patient may be able to adjust the insulin doses to coincide with meals and exercise.

Regular insulin is fast-acting and starts to work within 15–30 minutes, with its peak glucose-lowering effect about two hours after it is injected. Its effects last for about four to six hours. NPH (neutral protamine Hagedorn) and Lente insulin are intermediate-acting, starting to work within one to three hours and lasting up to 18–26 hours. Ultra-lente is a long-acting form of insulin that starts to work within four to eight hours and lasts 28–36 hours.

Hypoglycemia, or low blood sugar, can be caused by too much insulin, too little food (or eating too late to coincide with the action of the insulin), alcohol consumption, or increased exercise. A patient with symptoms of hypoglycemia may be hungry, cranky, confused, and tired. The patient may become sweaty and shaky. Left untreated, the patient can lose consciousness or have a seizure. This condition is sometimes called an insulin reaction and should be treated by giving the patient something sweet to eat or drink like a candy, sugar cubes, juice, or another high sugar snack.

Transplantation of a healthy pancreas into a diabetic patient is a successful treatment, however, this transplant is usually done only if a kidney transplant is performed at the same time. Although a pancreas transplant is possible, it is not clear if the potential benefits outweigh the risks of the surgery and drug therapy needed.

Alternatives

Since diabetes can be life-threatening if not properly managed, patients should not attempt to treat this condition without medical supervision. A variety of alternative therapies can be helpful in managing the symptoms of diabetes and supporting patients with the disease. **Acupuncture** can help relieve the pain associated with **diabetic neuropathy** by stimulation of certain points. A qualified practitioner should be consulted. Herbal remedies also may be helpful in managing diabetes. Although there is no herbal substitute for insulin, some herbs may help adjust blood sugar levels or manage other diabetic symptoms. Some options include:

- fenugreek (*Trigonella foenum-graecum*) has been shown in some studies to reduce blood insulin and glucose levels while also lowering cholesterol
- bilberry (*Vaccinium myrtillus*) may lower blood glucose levels, as well as help to maintain healthy blood vessels
- garlic (*Allium sativum*) may lower blood sugar and cholesterol levels
- onions (*Allium cepa*) may help lower blood glucose levels by freeing insulin to metabolize them
- cayenne pepper (*Capsicum frutescens*) can help relieve pain in the peripheral nerves (a type of diabetic neuropathy)
- ginkgo (*Ginkgo biloba*) may maintain blood flow to the retina, helping to prevent diabetic retinopathy

Any therapy that lowers stress levels also can be useful in treating diabetes by helping to reduce insulin requirements. Among the alternative treatments that

aim to lower stress are **hypnotherapy**, **biofeedback**, and **meditation**.

Prognosis

Uncontrolled diabetes is a leading cause of blindness, end-stage renal disease, and limb amputations. It also doubles the risks of heart disease and increases the risk of stroke. Eye problems including **cataracts**, **glaucoma**, and diabetic retinopathy also are more common in people with diabetes.

Diabetic **peripheral neuropathy** is a condition where nerve endings, particularly in the legs and feet, become less sensitive. Diabetic foot ulcers are a particular problem since the patient does not feel the pain of a blister, callous, or other minor injury. Poor blood circulation in the legs and feet contribute to delayed wound healing. The inability to sense pain along with the complications of delayed wound healing can result in minor injuries, blisters, or callouses becoming infected and difficult to treat. In cases of severe infection, the infected tissue begins to break down and rot away. The most serious consequence of this condition is the need for **amputation** of toes, feet, or legs due to severe infection.

Heart disease and **kidney disease** are common complications of diabetes. Long-term complications may include the need for **kidney dialysis** or a kidney transplant due to kidney failure.

Babies born to diabetic mothers have an increased risk of **birth defects** and distress at birth.

Prevention

Research continues on diabetes prevention and improved detection of those at risk for developing diabetes. While the onset of type 1 diabetes is unpredictable, the risk of developing type 2 diabetes can be reduced by maintaining ideal weight and exercising regularly. The physical and emotional stress of surgery, illness, pregnancy, and alcoholism can increase the risks of diabetes, so maintaining a healthy lifestyle is critical to preventing the onset of type 2 diabetes and preventing further complications of the disease.

Diabetic foot infections

Definition

Diabetic foot infections are infections that develop in the skin, muscles, or bones of the foot because of the nerve damage and poor circulation that is associated with diabetes.

Description

People who have diabetes have a greater than average chance of developing foot infections. Because a person who has diabetes may not feel foot **pain** or discomfort, problems can remain undetected until **fever**, weakness, or other signs of systemic infection appear. As a result, even minor irritations occur more often, heal more slowly, and are more likely to result in serious health problems.

With diabetes, foot infections occur more frequently because the disease causes nervous system changes and poor circulation. Because the nerves that control sweating no longer work well, the skin of the feet can become very dry and cracked, and calluses tend to occur more frequently and build up faster. If not trimmed regularly, these calluses can turn into open sores or **ulcers**. Because diabetic nerve damage can cause loss of sensation (neuropathy), if the feet are not regularly inspected, an ulcer can quickly become infected and, if not treated, may result in the death of tissue (**gangrene**) or **amputation**.

Persons with diabetes often suffer from foot ulcers, as shown above. *(Custom Medical Stock Photo, Inc.)*

Demographics

Diabetic foot infections are a serious, and growing, problem in many parts of the world, especially in the United States where the rate of diabetes is increasing. The U.S. Centers for Disease Control and Prevention (CDC) estimates that 29 million adults or 12.3% of Americans had diabetes in 2014. A very large proportion of these individuals are likely to have one or more foot infections related to their diabetes, with the problem becoming more common as individuals age. More than 60% of all nontraumatic amputations of the toes, feet, or legs performed in the United States are performed on individuals with diabetes, resulting in more than 60,000 total lower-limb amputations related to diabetes each year.

The risk of diabetic foot infection is greatest for people who are over the age of 60 and for those who have one or more of the following conditions:

- poorly controlled diabetes
- foot ulcers
- laser treatment for changes in the retina
- kidney or vascular disease
- loss of sensation (neuropathy)

Causes and symptoms

Bacteria can cause an infection through small cracks (fissures) that can develop in the dry skin around the heel and on other parts of the foot or through corns, calluses, blisters, hangnails, or ulcers. If not treated, the bacterial infection can destroy skin, tissue, and bone or spread throughout the body.

Common sites of diabetic foot infections include the following:

- blisters, corns, or calluses that bleed beneath the skin

- bunions, hammertoes, or other abnormalities in the bones of the foot
- scar tissue that has grown over the site of an earlier infection
- foot ulcers caused by pressure, nerve damage, or poor circulation. These ulcers occur most often over the ball of the foot, on the bottom of the big toe, or on the sides of the foot due to poorly fitting shoes.
- injuries that tear or puncture the skin

Diagnosis

A podiatrist (a physician who specializes in the treatment of the foot) or the doctor who normally treats the patient's diabetes will treat the infection. An x ray of the foot is taken to determine whether the bone has become infected. A sample from the wound is cultured to identify the organism that is causing the infection so that the appropriate antibiotic can be selected.

Treatment

From the results of the culture, the appropriate antibiotic will be prescribed. Any dead or infected tissue will be surgically removed (debrided) and, if necessary, a cast and/or special shoes may be used to protect the area. In addition, patients will be instructed to keep off their feet. If the ulcer does not heal, the physician may perform surgery to increase blood flow to the foot. In severe cases, a portion of the toe, foot, or leg must be amputated. It is also important for patients to practice good diabetes control and keep blood glucose levels from getting too high in order to reduce the risk of foot infections and other effects of diabetes.

Prognosis

Without proper treatment, diabetic foot infections can lead to serious illness, gangrene, amputation, and even death if the infection spreads throughout the body. If treated properly and patients practice good foot hyngiene and care, the prognosis is generally good.

Prevention

Diabetic individuals can do the following to prevent the occurrence of foot infections:

- control blood glucose level and not allow it to get too high
- avoid smoking
- keep blood pressure and cholesterol under control

KEY TERMS

Fissure—A deep crack.

Neuropathy—An abnormality of the nerves outside the brain and spinal cord.

Ulcer—A sore or lesion.

- exercise to stimulate blood flow
- keep feet clean, dry, and warm
- check feet every day for blisters, scratches, and skin that is hard, broken, inflamed, or feels hot or cold when touched
- after bathing, carefully dry feet and apply thin coat of petroleum jelly or hand cream to prevent dry skin from cracking
- use a pumice stone and emery board to trim calluses
- treat a sore or ulcer immediately if one develops
- do not walk around with bare feet, even at home
- wear socks without elastic bands around the top, as these can decrease circulation to the feet

Maureen Haggerty
REVISED BY TISH DAVIDSON, AM

Diabetic ketoacidosis

Definition

Diabetic ketoacidosis is a dangerous complication of **diabetes mellitus** in which the chemical balance of the body becomes far too acidic.

Description

Diabetic ketoacidosis (DKA) always results from a severe insulin deficiency. Insulin is the hormone secreted by the body to lower the blood sugar levels when they become too high. Diabetes mellitus is the disease resulting from the inability of the body to produce or respond properly to insulin, required by the body to convert glucose to energy. In childhood diabetes, DKA complications represent the leading cause of death, mostly due to the accumulation of abnormally large amounts of fluid in the brain (cerebral **edema**). DKA combines three major features: hyperglycemia, meaning excessively high blood sugar kevels; hyperketonemia, meaning an overproduction of ketones by the body; and acidosis, meaning that the blood has become too acidic.

Insulin deficiency is responsible for all three conditions: the body glucose goes largely unused since most cells are unable to transport glucose into the cell without the presence of insulin; this condition makes the body use stored fat as an alternative source instead of the unavailable glucose for energy, a process that produces acidic ketones, which build up because they require insulin to be broken down. The presence of excess ketones in the bloodstream in turn causes the blood to become more acidic than the body tissues, which creates a toxic condition.

Causes and symptoms

DKA is most commonly seen in individuals with type 1 diabetes, under 19 years of age and is usually caused by the interruption of their insulin treatment or by acute infection or **trauma**. A small number of people with type 2 diabetes also experience ketoacidosis, but this is rare given the fact that type 2 diabetics still produce some insulin naturally. When DKA occurs in type 2 patients, it is usually caused by a decrease in food intake and an increased insulin deficiency due to hyperglycemia.

Some common DKA symptoms include:

- high blood sugar levels
- frequent urination (polyuria) and thirst
- fatigue and lethargy
- nausea
- vomiting
- abdominal pain
- fruity odor to breath
- rapid, deep breathing
- muscle stiffness or aching
- coma

Diagnosis

Diagnosis requires the demonstration of hyperglycemia, hyperketonemia, and acidosis. DKA is established if the patient's urine or blood is strongly positive for glucose and ketones. Normal glucose levels in a non-diabetic person on average range from 80–110 mg/dl. A person with diabetes will typically fluctuate outside those parameters. DKA glucose levels exceed 250 mg/dl and can reach 400–800 mg/dL. A low serum bicarbonate level (usually below 15 mEq/L) is also present, indicative of acidosis.

A blood test or **urinalysis** can quickly determine the concentration of glucose in the bloodstream. Test strips are available to patients commercially can submerge in urine to detect the presence or concentration of ketones.

Treatment

Ketoacidosis is treated under medical supervision and usually in a hospital setting.

Basic treatment includes:

- administering insulin to correct the hyperglycemia and hyperketonemia

KEY TERMS

Acidosis—A condition that causes the pH of the blood to drop and become more acidic.

Diabetes mellitus—Disease characterized by the inability of the body to produce or respond properly to insulin, required by the body to convert glucose to energy.

Edema—The presence of abnormally large amounts of fluid in the intercellular tissue spaces of the body.

Glucose—The type of sugar found in the blood.

Hyperglycemia—Condition characterized by excessively high levels of glucose in the blood, and occurs when the body does not have enough insulin or cannot use the insulin it does have to turn glucose into energy. Hyperglycemia is often indicative of diabetes that is out of control.

Hyperketonemia—Condition characterized by an overproduction of ketones by the body.

Hypoglycemia—Lower than normal levels of glucose in the blood.

Hypokalemia—A deficiency of potassium in the blood.

Insulin—A hormone secreted by the pancreas in response to high blood sugar levels that induces hypoglycemia. Insulin regulates the body's use of glucose and the levels of glucose in the blood by acting to open the cells so that they can intake glucose.

Ketones—Poisonous acidic chemicals produced by the body when fat instead of glucose is burned for energy. Breakdown of fat occurs when not enough insulin is present to channel glucose into body cells.

Lactic acidosis—A serious condition caused by the build up of lactic acid in the blood, causing it to become excessively acidic. Lactic acid is a by-product of glucose metabolism.

Metabolism—The sum of all chemical reactions that occur in the body resulting in growth, transformation of foodstuffs into energy, waste elimination, and other bodily functions.

Polyuria—Excessive secretion of urine.

Type 1 diabetes—Also called juvenile diabetes. Type 1 diabetes typically begins early in life. Affected individuals have a primary insulin deficiency and must take insulin injections.

Type 2 diabetes—Type 2 diabetes is the most common form of diabetes and usually appears in middle aged adults. It is often associated with obesity and may be delayed or controlled with diet and exercise.

- replacing fluids lost through excessive urination and vomiting intravenously
- balancing electrolytes to re-establish the chemical equilibrium of the blood and prevent potassium deficiency (hypokalemia) during treatment
- treatment for any associated bacterial infection

Prognosis

With proper medical attention, DKA is almost always successfully treated. The DKA mortality rate is about 10%. **Coma** on admission adversely affects the prognosis. The major causes of death are circulatory collapse, **hypokalemia**, infection, and cerebral edema.

Prevention

Once diabetes has been diagnosed, prevention measures to avoid DKA include regular monitoring of blood glucose, administration of insulin, and lifestyle maintenance. Glucose monitoring is especially important during periods of **stress**, infection, and trauma when glucose concentrations typically increase as a response to these situations. Ketone tests should also be performed during these periods or when glucose is elevated.

Diabetic neuropathy

Definition

Diabetic neuropathy is a nerve disorder caused by **diabetes mellitus**. Diabetic neuropathy may be diffuse, affecting several parts of the body, or focal, affecting a specific nerve and part of the body.

Demographics

The longer a person has diabetes, the more likely the development of one or more forms of neuropathy. Approximately 60–70% of patients with diabetes have neuropathy, but only about 5% experience painful symptoms.

Description

The nervous system consists of two major divisions: the central nervous systems (CNS), which includes the brain, the cranial nerves, and the spinal cord, and the peripheral nervous system (PNS), which includes the nerves that link the CNS with the sensory organs, muscles, blood vessels, and glands of the body. These peripheral nerves are either motor, meaning that they are involved in motor activity such as walking, or sensory, meaning that they carry sensory information back to the CNS. The PNS also works with the CNS to regulate involuntary (autonomic) processes such as breathing, heartbeat, blood pressure, etc.

There are two types of diffuse diabetic neuropathy that affect different nervous system functions. Diffuse **peripheral neuropathy** primarily affects the limbs, damaging the nerves of the feet and hands. Autonomic neuropathy is the other form of diffuse neuropathy and it affects the heart and other internal organs.

Focal—or localized—diabetic neuropathy affects specific nerves, most commonly in the torso, leg, or head.

Diabetic neuropathy can lead to muscular weakness, loss of feeling or sensation, and loss of autonomic functions such as digestion, erection, bladder control, and sweating among others.

Causes and symptoms

The exact cause of diabetic neuropathy is not known. Researchers believe that the process of nerve damage is related to high glucose concentrations in the blood that could cause chemical changes in nerves, disrupting their ability to effectively send messages. High blood glucose is also known to damage the blood vessels that carry oxygen and other nutrients to the nerves. In addition, some people may have a genetic predisposition to develop neuropathy.

There is a wide range of symptoms associated with diabetic neuropathy, and they depend on which nerves and parts of the body are affected, as well as the type of neuropathy present. Some patients have very mild symptoms, while others are severely disabled.

Common symptoms of diffuse peripheral neuropathy include:

- numbness and feelings of tingling or burning
- insensitivity to pain
- needle-like jabs of pain
- extreme sensitivity to touch
- loss of balance and coordination

Common symptoms of diffuse autonomic neuropathy include:

- impaired urination and sexual function
- bladder infections
- stomach disorders, due to the impaired ability of the stomach to empty (gastric stasis)
- nausea, vomiting, and bloating
- dizziness, lightheadedness, and fainting spells

KEY TERMS

Central nervous system (CNS)—Part of the nervous system consisting of the brain, cranial nerves, and spinal cord. The brain is the center of higher processes, such as thought and emotion, and is responsible for the coordination and control of bodily activities and the interpretation of information from the senses. The cranial nerves and spinal cord link the brain to the peripheral nervous system.

Diabetes mellitus—Disease characterized by the inability of the body to produce or respond properly to insulin, required by the body to convert glucose to energy.

Glucose—The type of sugar found in the blood.

Peripheral nervous system (PNS)—One of the two major divisions of the nervous system. PNS nerves link the central nervous system with sensory organs, muscles, blood vessels, and glands.

- loss of appetite

Common symptoms of focal neuropathy include:

- pain in the front of a thigh
- severe pain in the lower back
- pain in the chest or stomach
- ache behind an eye
- double vision
- paralysis on one side of the face

In severe diabetic neuropathy loss of sensation can lead to injuries that are unnoticed, progressing to infections, ulceration and possibly **amputation**.

Diagnosis

Examination

The diagnosis of neuropathy is based on the symptoms that present during a physical exam. **Pain** assessment is usually the first step. Patients may have more than one type of pain, and the history helps the doctor determine whether a the pain has a neuropathic cause.

Tests

Based on finding during the physical exam, additional testing may be performed:

- screening tests for lost sensation
- nerve conduction studies to check the flow of electric current through a nerve
- electromyography (EMG) to see how well muscles respond to electrical impulses transmitted by nearby nerves
- ultrasound to show how the bladder and other parts of the urinary tract are functioning
- a nerve biopsy

Specialists who treat diabetic neuropathy include:

- neurologists: specialists in nervous system disorders
- urologists: specialists in urinary tract disorder
- gastroenterologists: specialists in digestive disorders
- podiatrists: specialists in caring for the feet

Treatment

Traditional

Treatment of diabetic neuropathy is usually focused on treating the symptoms associated with the neuropathy and addressing the underlying cause by improving the control of blood sugar levels, which may heal the early stages of neuropathy.

Drugs

There is no cure for the permanent nerve damage caused by neuropathy. To help control pain, drug therapy is normally used. The choice of proven drug therapies has broadened during the past decade. Pain medication, such as the topical skin cream capsaicin, is usually no stronger than codeine because of the potential for **addiction** with long-term use of such drugs.

Four main classes of drugs are available for **pain management**, alone or in combination: tricyclic antidepressants (Imipramine, Nortriptyline), narcotic **analgesics** (Morphine), anticonvulsants (Carbamazepine, Gabapentin), and antiarrhythmics.

Prognosis

Early stage diabetic neuropathy can usually be reversed with good glucose control. Once nerve damage has occurred it cannot be reversed. The prognosis is largely dependent on the management of the underlying condition, diabetes, which may halt the progression of the neuropathy and improve symptoms. Recovery, if it occurs, is slow.

Prevention

Tight glucose control and the avoidance of alcohol and cigarettes help protect nerves from damage.

Diaper rash

Definition

Dermatitis of the buttocks, genitals, lower abdomen, or thigh folds of an infant or toddler is commonly referred to as diaper rash.

Demographics

Diaper rash is believed to occur with the same frequency in infants who wear cloth or disposable diapers. It occurs most frequently in infants between eight and ten months of age, although it can occur in any child who wears diapers, generally from birth through about age three. It is estimated that about 10% of children will experience some significant diaper rash, although many more children will experience mild diaper rash at some time.

Description

Diaper rash is a term that covers a broad variety of skin conditions that occur on the same area of the body. Some babies are more prone to diaper rash than others.

Frequently a flat, red rash is caused by simple chafing of the diaper against tender skin, initiating a friction rash. This type of rash is not seen in the skin folds. It may be more pronounced around the edges of the diaper, at the waist and leg bands. The baby generally does not appear to experience much discomfort. Sometimes the chemicals or detergents in the diaper are contributing factors and may result in **contact dermatitis**. These **rashes** should clear up easily with proper attention. Ignoring the condition may lead to a secondary infection that is more difficult to resolve.

Baby with severe diaper rash. *(Custom Medical Stock Photo, Inc.)*

Friction of skin against itself can cause a rash in the baby's skin folds, called intertrigo. This rash appears as reddened areas that may ooze and is often uncomfortable when the diaper is wet. Intertrigo can also be found on other areas of the body where there are deep skin folds that tend to trap moisture.

Seborrheic dermatitis is the diaper area equivalent of cradle cap. It is scaly and greasy in appearance and may be worse in the folds of the skin.

Yeast, or candidal dermatitis, is the most common infectious cause of diaper rash. The affected areas are raised and quite red with distinct borders, and satellite lesions may occur around the edges. Yeast is part of the normal skin flora, and is often an opportunistic invader when simple diaper rash is left untreated. It is particularly common after treatment with **antibiotics**, which kill the good bacteria that normally keep the yeast population in check. Usual treatments for diaper rash often are not sufficient to treat this rash. Repeated or difficult to resolve episodes of yeast infection may warrant further medical attention, since this is sometimes associated with diabetes or immune system problems.

Another infectious cause of diaper rash is **impetigo**. This bacterial infection is characterized by blisters that ooze and crust.

Causes and symptoms

The outside layer of skin normally forms a protective barrier that prevents infection. One of the primary causes of dermatitis in the diaper area is prolonged skin contact with wetness. Under these circumstances, natural oils are stripped away, the outer layer of skin is damaged, and there is increased susceptibility to infection by bacteria or yeast.

Diagnosis

The presence of red, blotchy skin or **skin lesions** in the diaper area means that the baby has diaper rash. However, there are several types of rash that may require specific treatment in order to heal. It is useful to be able to distinguish them by appearance.

A baby with a rash that does not clear up within two to three days with home treatment or a rash with pustules, blisters, or bleeding should be seen by a healthcare professional for further evaluation. A rash

accompanied by other symptoms such as a **fever**, rash on other areas of the body, or **vomiting** should also be seen quickly by the baby's doctor.

Treatment

Traditional

Antibiotics are generally prescribed for rashes caused by bacteria, particularly impetigo. This may be a topical or oral formulation, depending on the size of the area involved and the severity of the infection.

Over-the-counter antifungal creams, such as Lotrimin, are often recommended to treat a rash resulting from yeast. If topical treatment is not effective, an oral antifungal may be prescribed.

Mild steroid creams, such as 0.5–1% hydrocortisone, can be used for seborrheic dermatitis and sometimes intertrigo. Prescription strength creams may be needed for short-term treatment of more stubborn cases.

Alternatives

In the event of suspected yeast, a tablespoon of cider vinegar can be added to a cup of warm water and used as a cleansing solution. This is dilute enough that it should not burn, but acidifies the skin pH enough to hamper yeast growth.

What the baby eats can make a difference in stool frequency and acidity. When adding a new food to the diet, the baby should be observed closely to see whether rashes are produced around the baby's mouth or anus. If this occurs, the new food should be discontinued.

Babies who are taking antibiotics are more likely to get rashes due to yeast. To help bring the good bacterial counts back to normal, *Lactobacillus bifidus* can be added to the diet. It is available in powder form from most health food stores.

Some herbal preparations can be useful for diaper rash. Calendula reduces inflammation, tightens tissues, and disinfects. It has been recommended for seborrheic dermatitis as well as for general inflammation of the skin. The ointment should be applied at each diaper change. Chickweed ointment can also be soothing for irritated skin and may be applied once or twice daily.

Home remedies

Good diaper hygiene will prevent or clear up many simple cases of diaper rash. Diapers should be checked very frequently and changed as soon as they are wet or soiled. Good air circulation is also important for healthy skin. Babies should have some time without wearing a diaper; a waterproof pad can be used to protect the bed or other surface. Rubber pants or other occlusive fabrics should not be used over the diaper area. There is no clear evidence that either cloth or disposable diapers are better at preventing diaper rash. It may be necessary for parents to experiment with diaper types to see if the baby's skin reacts better to cloth or disposable ones or if a particular brand works especially well. If the baby is wearing cloth diapers, they should be washed in a mild detergent and double rinsed. Using a larger size of diaper than normal until the rash heals can help speed healing and increase the baby's comfort.

The diaper area should be cleaned with something mild, even plain water. Some wipes contain alcohol or chemicals that can be irritating for some babies. Plain water may be the best cleansing substance when there is a rash. Using warm water in a spray bottle (or giving a quick bath) and then lightly patting the skin dry can produce less skin **trauma** than using wipes.

Barrier ointments can be valuable to treat rashes. Those that contain zinc oxide are especially effective. These creams and ointments protect already irritated skin from the additional insult of urine and stool, particularly if the baby has **diarrhea**. It is generally not recommended to use a talcum powder when changing the diaper, as inhaling the powder has been found to cause damage to infant's lungs.

KEY TERMS

Dermatitis—Inflammation of the skin.

Pustule—A small raised pimple or blister-like swelling of the skin that contains pus.

Prognosis

Treated appropriately, diaper rash resolves fairly quickly if there is no underlying health problem or skin disease.

Prevention

Frequent diaper changes are important to keep the skin dry and healthy. Application of powders

WWW.BOOKBAZ.IR

and ointments is not necessary when there is no rash. Finding the best combination of cleansing and diapering products for the individual baby will also help to prevent diaper rash.

Judith Turner

REVISED BY TISH DAVIDSON, AM

Diaphragm (birth control)

Definition

Diaphragms are dome-shaped barrier methods of **contraception** that block sperm from entering the uterus. They are made of latex (rubber) and formed like a shallow cup. Since vaginas vary in size, each patient will need to be fitted by a doctor or nurse with a diaphragm that conforms to the shape and contour of the vagina as well as the strength of the muscles in the vaginal walls. Diaphragms must be used with spermicidal cream or jelly. The device should cause no discomfort, and neither the woman nor her partner should feel that it is there.

Purpose

The purpose of a diaphragm is to prevent access to the womb (uterus) by the sperm and thus prevent conception. The level of effectiveness is about 95%.

Precautions

Each client will undergo a **physical examination** and a Pap smear. If these are normal, the physician will fit the patient for the device and give instructions on how to insert, remove, and clean the object. She will also be taught the signs and symptoms of potential complications.

Description

Prior to insertion, the inside of the dome and the rim are covered with a thick layer (perhaps a tablespoon) of a spermicide that is compatible with the diaphragm being used. The domed area covers the opening into the uterus (cervix) and keeps the spermicide in place. As a result, any sperm that might get under the diaphragm will be destroyed.

Diaphragms may be inserted 2–3 hours prior to intercourse, and must be left in place for 6–8 hours following sexual relations. During this time the woman may not swim, bathe, or douche, but she may shower. If she desires to have intercourse again before the 6–8 hours have passed, the diaphragm should not be removed. Instead, an applicator full of spermicide should be deposited into the vagina.

A diaphragm will last for a year or more. It should be examined weekly for holes. This can be done by holding it up to the light or filling it with water.

Preparation

Before inserting the diaphragm, the woman should empty her bladder and wash her hands with soap and water. The device should be checked for leaks by filling it with water or holding it up to the light. A spermicidal jelly is then applied to the inside and outside, and especially around the rim. While standing with one foot elevated on a chair or step, lying down, or squatting, the woman folds the diaphragm inward toward the middle and inserts it into the vagina as far as it will go.

Aftercare

When removed, the diaphragm should be washed with a mild soap and water. After being

KEY TERMS

Spermicide—A substance that kills sperm.

Toxic shock syndrome—An uncommon, but potentially fatal, disease that has been associated with the use of diaphragms and vaginal tampons. The symptoms include high fever, vomiting, and diarrhea.

dried, it can be dusted with corn starch before being returned to its container. The diaphragm should always be stored away from sunlight and heat in a cool, dry place. It should not be washed with harsh or perfumed soaps or used with perfumed powders because either of these substances can damage the diaphragm.

Risks

Although rare, wearing the diaphragm longer than the recommended time can result in **toxic shock syndrome**. The signs and symptoms of this serious illness include sudden onset of high **fever**, **vomiting**, **diarrhea**, **dizziness**, faintness, weakness, aching muscles and joints, and rash. The doctor must be notified immediately if any of these conditions appear. An allergic reaction to the spermicide or the material from which the device is made is also possible. Diaphragm use is also associated with an increased risk of bladder infections.

It should be noted that the diaphragm can become dislodged during intercourse, which could result in an unwanted **pregnancy**. To ensure a secure fit, a woman should be examined for a refitting if she gains or loses more than 10 lbs (4.5 kg), or after she gives birth.

Results

Consumers can expect an efficiency rate of about 95% in preventing pregnancy. Using a male condom in conjunction with the diaphragm decreases the potential for pregnancy. Diaphragms provide no protection against **AIDS** or other sexually transmitted diseases.

Diaphragmatic hernia *see* **Hernia**

Diarrhea

Definition

The World Health Organization (WHO) defines diarrhea (sometimes spelled diarrhoea) as "three or more loose or liquid stools per day, or more frequently than is normal for the individual." Researchers have also found that diarrhea best correlates with an increase in stool weight: Stool weights above 10 oz (300 g) per day generally indicates diarrhea. The increase in weight is mainly due to excess water, which normally makes up 60–85% of fecal matter. In this way, true diarrhea is distinguished from diseases that cause only an increase in the number of bowel movements (hyperdefecation) or incontinence (involuntary loss of bowel contents).

Physicians also classify diarrhea into acute or chronic varieties. Acute diarrhea lasts one or two weeks, and chronic continues for longer than two or three weeks. Acute diarrhea is also sometimes subdivided into acute watery diarrhea and acute bloody diarrhea, the latter of which is also called **dysentery**.

Description

Although diarrhea is often a mild and temporary problem, it can be a serious, even life-threatening problem, especially for individuals living in developing nations, where it accounts for most deaths occur among children under five years of age. Diarrhea can usually be prevented through the provision of clean drinking water, proper sanitation, and good hygiene, and rapid diagnosis and treatment can eliminate much of the suffering associated with these more devastating diarrheal bouts.

While acute diarrhea is associated with many of the deaths due to diarrheal diseases, chronic diarrhea can also have a significant effect on health, as well as on social and economic wellbeing. Patients with **celiac**

WWW.BOOKBAZ.IR

disease, inflammatory bowel disease, and other prolonged diarrheal illnesses develop nutritional deficiencies that diminish growth and immunity. Chronic diarrhea can affect social interaction and result in the loss of many working hours.

Demographics

There are nearly 1.7 billion annual cases of diarrheal disease globally, according to WHO. While diarrhea is a mild, limited annoyance to many people, especially those in developed countries, it can be much worse in developing nations, and in fact can be fatal. In developing nations, most deaths occur among children under five years of age. Globally, diarrheal disease is the second leading cause of death in this age group, leading to about 760,000 fatalities per year.

Causes and symptoms

Symptoms

Diarrhea occurs because more fluid passes through the large intestine (colon) than that organ can handle. Although the colon can absorb several times more fluid every day than the human body requires, it can become overwhelmed. When this happens, diarrhea results.

In diarrhea, the number of bowel movements can vary—up to 20 or more per day. In some patients, blood or pus is present in the stool. Bowel movements may be difficult to flush (they may float) or may contain undigested food material.

All or none of the following symptoms may be present, depending on the disease causing the diarrhea: **fever**, nausea, **vomiting**, and abdominal **pain**.

Causes

Diarrhea is caused by infections or illnesses that either lead to excess production of fluids or prevent absorption of fluids. Also, certain substances in the colon, such as fats and bile acids, can interfere with water absorption and cause diarrhea. In addition, rapid passage of material through the colon can hinder the colon's ability to absorb fluids and can also result in diarrhea.

The most common causes of acute diarrhea are viral or bacterial infections, **food poisoning**, and medications. Medications, especially **antibiotics** and **antacids**, are a frequent and sometimes overlooked cause. Less often, various sugar-free foods, which sometimes contain poorly absorbable materials, cause diarrhea.

Chronic diarrhea is frequently due to many of the same causes of the shorter episodes, such as infections and medications, but symptoms last longer. Some infections can become chronic. This condition occurs mainly with parasitic infections, including such as *Giardia* or when patients have altered immunity as is associated with diseases such as acquired immune deficiency syndrome (**AIDS**).

The following are the more usual causes of chronic diarrhea:

- food allergy
- inflammatory bowel disease, such as Crohn's disease and ulcerative colitis
- lactose intolerance
- malabsorption syndromes (celiac and Whipple's disease)
- endocrine or hormonal abnormalities, such as thyroid and diabetes mellitus
- colon cancer and other bowel tumors
- AIDS or other immune disorders
- other (such as alcohol, microscopic colitis, radiation, and surgery)

Complications

The major effects of diarrhea are **dehydration**, **malnutrition**, and weight loss. Signs of dehydration may not be readily noticeable, but increasing thirst, **dry mouth**, weakness or lightheadedness (particularly if worsening on standing), or a darkening/decrease in urination are suggestive. Severe dehydration leads to changes in the body's chemistry and could become life threatening. Dehydration from diarrhea can result in kidney failure, neurological symptoms, arthritis, and skin problems.

Diagnosis

Most cases of acute diarrhea never need diagnosis or treatment, as many are mild and produce few problems. Patients do, however, need prompt medical evaluation if they have fever of more than 102°F (38.9°C), signs of dehydration, bloody bowel movements, severe abdominal pain, or known immune disease, or have used antibiotics.

When diagnostic tests are needed, the most useful are **stool culture** and examination for parasites, but these are often negative and a cause cannot be found in a large number of patients. The earlier that cultures

are performed, the greater the chance of obtaining a positive result.

For those patients with a history of antibiotic use in the preceding two months, stool samples need to be examined for the toxins that cause **antibiotic-associated colitis**. Tests are also available to examine stool samples for microscopic amounts of blood and for cells that indicate severe inflammation of the colon. Examination with an endoscope (a lighted device used to check a body cavity) is sometimes helpful in determining severity and extent of inflammation. Tests to check changes in blood chemistry and a **complete blood count** (CBC) are also often performed.

Chronic diarrhea is quite different, and most patients with this condition receive some degree of testing. Many exams are the same as for an acute episode, as some infections and parasites cause both types of diarrhea. Medical professionals will take a patient history to evaluate medication use, dietary changes, family history of illnesses, and other symptoms. Both prescription and over-the-counter medications can contain additives, such as lactose and sorbitol, which can produce diarrhea in sensitive individuals. Review of **allergies** or skin changes may also point to a cause. Social history may indicate whether **stress** is playing a role or may identify activities that can be associated with diarrhea (for example, diarrhea that occurs in runners).

A combination of stool, blood, and urine tests may be needed in the evaluation of chronic diarrhea; in addition a number of endoscopic and x-ray studies are frequently required. Key points in determining the severity of symptoms are weight loss of more than 10 lb (4.5 kg), blood in the stool, and nocturnal diarrhea (symptoms that awaken the patient from sleep).

Treatment

Treatment is ideally directed toward correcting the cause, but the first aim is to prevent or treat dehydration and nutritional deficiencies. Medical professionals will recommend fluid and nutrient replacement, which may be commercial products or homemade preparations, based upon whether the patient can take oral feedings and the severity of fluid losses. These preparations are called oral rehydration solutions (ORSs). In some cases, physicians may recommend intravenous fluids.

When feasible, food intake should be continued even in those with acute diarrhea. A physician should be consulted as to what type and how much food is permitted. Medical professionals may also direct patients, particularly children, to take supplements for a week or two, because studies have shown that zinc can reduce the duration and severity of diarrhea and can also decrease the likelihood that diarrhea will recur over the following two to three months.

Over-the-counter medications, such as loperamide (Imodium) or bismuth subsalicylate (Pepto-Bismol or Kaopectate) are often useful, but their use is limited or even contraindicated in most individuals with bacteria-caused acute diarrhea, especially in those patients with high fever or bloody bowel movements. These agents should not be taken without the advice of a physician.

Other treatments are available, depending on the cause of symptoms. Examples include the bulk agent psyllium, which helps some patients by absorbing excess fluid and solidifying stools, and cholestyramine, which binds bile acids and is effective in treating bile salt-induced diarrhea. Low-fat **diets** or more easily digestible fat is useful in some patients. New **antidiarrheal drugs** that decrease excessive secretion of fluid by the intestinal tract is another approach for some diseases. Avoidance of medications or other products that are known to cause diarrhea (such as lactose) is curative in some but should be discussed with a physician.

Alternatives

Once the cause of diarrhea has been identified, some patients may prefer alternative treatments. One effective approach to preventing and treating diarrhea involves oral supplementation of aspects of the normal flora in the colon with the yeasts *Lactobacillus acidophilus*, *L. bifidus*, or *Saccharomyces boulardii*. In clinical settings, these biotherapeutic agents have repeatedly been helpful in the resolution of diarrhea, particularly diarrhea associated with antibiotic use.

Prognosis

Prognosis is related to the cause of the diarrhea. For most individuals in developed countries, a bout of acute, infectious diarrhea may be uncomfortable but is not life threatening. In some cases, particularly in developing areas but also sometimes in industrialized countries, serious complications and death can occur.

WWW.BOOKBAZ.IR

KEY TERMS

Anti-motility medications—Medications such as loperamide (Imodium), diphenoxylate (Lomotil), or medications containing codeine or narcotics that decrease the ability of the intestine to contract. These can worsen the condition of a patient with dysentery or colitis.

Colitis—Inflammation of the colon.

Endoscope—A thin flexible tube that uses a lens or miniature camera to view various areas of the gastrointestinal tract. Both diagnosis, through biopsies or other means, and therapeutic procedures can be done with this instrument.

Endoscopy—The performance of an exam using an endoscope is known generally as endoscopy.

Lactose intolerance—An inability to properly digest milk and dairy products.

Oral rehydration solution (ORS)—A liquid preparation developed by the World Health Organization that can decrease fluid loss in persons with diarrhea. Originally developed to be prepared with materials available in the home, commercial preparations have recently come into use.

Among patients with chronic symptoms, approximately 90% receive a specific diagnosis. In some, however, no specific cause is found and only treatment with bulk agents or anti-motility agents is indicated.

Prevention

Good hygiene, food-handling, and sanitation practices, along with the consumption of clean water are important in preventing diarrhea. Traveler's diarrhea can be avoided by refusing certain foods and drinks that utilize water, such as rinsed lettuce or ice tea made with local water, which may contain bacteria that are not familiar to the person's system and may lead to diarrhea.

The American Academy of Pediatrics also recommends that children get the rotavirus vaccine as part of their normal immunizations. This oral vaccine protects children from the highly contagious rotavirus, which is the leading cause of severe diarrhea among young children. The vaccine comes in two brands: RotaTeq (RV5), which requires three doses recommended to be administered when the baby is two, four, and six months old; and Rotarix (RV1), which requires two doses recommended to be administered at two and four months old.

Diet and disease prevention

Definition

Research has shown that diet has a tremendous impact on short- and long-term health. Poor diet can lead to nutritional deficiencies and chronic diseases such as **obesity**, **diabetes mellitus** type 2, **stroke**, **osteoporosis**, and coronary **heart disease**. A good diet combined with **exercise** promotes a healthy weight, reduces many health risks, and increases both physical and mental well-being.

Description

The position of the Academy of **Nutrition** and Dietetics (formerly the American Dietetic Association) on the role of nutrition and diet in health promotion and disease prevention programs includes steps for primary, secondary, and tertiary prevention. These steps include the following guidelines:

- Primary prevention (health promotion): Health promotion is a population-based approach that encourages behaviors for better health. For example, taking nutrition classes at a local adult education center would be considered a primary prevention measure.
- Secondary prevention (risk appraisal and risk reduction): For people at risk of illness who are beginning to encounter health-related problems, secondary prevention encompasses risk appraisal and screening to detect preclinical disease and early intervention to promote health and well-being. Cholesterol screening for people with a family history of cardiovascular disease is an example of a secondary prevention measure.
- Tertiary prevention (treatment and rehabilitation): For people experiencing illness, injury, or disability, tertiary prevention includes treatment and rehabilitation to promote maximum health and prevent further disability and secondary conditions resulting from the initial health problem. Examples of tertiary prevention include medical nutrition therapy or diabetes education for people diagnosed with type 2 diabetes mellitus.

The seventh edition of the *Dietary Guidelines for Americans*, published in 2010 by the U.S. Department of Agriculture (USDA) and Health and Human Services (HHS), provides an overall view of good nutrition along with specific recommendations for improved dietary habits. These **dietary guidelines** include:

- Make half your plate fruits and vegetables.
- Switch to fat-free or low-fat (1%) milk (for people over age 2).
- Drink water instead of sugary drinks.
- Compare sodium in foods like soup, bread, and frozen meals and choose the foods with lower numbers.
- Avoid oversized portions.
- Enjoy your food, but eat less.

More than 100 years ago, in 1894, the USDA published its first set of national nutrition guidelines. MyPlate, replacing the former MyPyramid, is the most recent set of guidelines. The MyPlate design was simplified from the food pyramid to help consumers visualize the actual breakdown of each meal. Half of the plate is devoted to vegetables and fruits; slightly less than one-quarter is made up of protein (no longer meat and beans); and the remaining amount is dedicated to grains. A side of dairy is also featured, and the previous "fats and oils" category is obsolete. The MyPlate ethos emphasizes lifestyle factors such as exercise in addition to nutrition.

MyPlate is intended to help Americans become more aware of what they eat and what their nutrient requirements are. It is designed to help people learn how to eat a healthy diet, live an active lifestyle, and maintain or gradually move in the direction of a healthy weight, which will reduce the risk of weight-related diseases. MyPlate personalizes the specific amounts needed in each category based on the individual's age, gender, and activity level.

WWW.BOOKBAZ.IR

The MyPlate website, ChooseMyPlate.gov, provides detailed information on the five food categories along with additional guidelines on oils, calories, and physical activity. MyPlate assumes that people will eat from all food categories. The personalized recommendations about quantities to eat for each group do not take into consideration special **diets** for people with diabetes or other diseases, nor do they apply to children younger than two.

Wheat, rice, oats, barley, and cornmeal are common grains in the American diet. Less familiar grains include buckwheat (also called kasha), amaranth, quinoa, sorghum, millet, rye, and triticale. Pasta, bread, oatmeal, breakfast cereals, grits, crackers, tortillas, and other foods made from grains are part of this group.

Grains are divided into two categories: whole grains and refined grains. MyPlate recommends that at least half of the grains an individual eats daily be whole grains. In whole grain, the whole kernel, including the bran and germ of the grain seed, is used or ground into flour. Examples of whole-grain products include whole-wheat flour; cracked wheat (bulgur); brown rice; wild rice; whole cornmeal; oatmeal; whole-wheat breads, pastas, and cereals; and popcorn.

In refined grains, the bran, or seed coating, and the germ, or center of the kernel, are removed during processing. This produces softer flour and removes oils from the grain. It also slows the spoilage process and increases the shelf life of refined-grain products. However, refining also removes dietary fiber, iron, and B-complex **vitamins**. Products made with refined grain often have B vitamins and iron added to replace some of what was lost by removing the germ and bran. **Calcium** is also added. These products are labeled as "enriched." Examples of refined-grain products include white flour, degermed cornmeal, white rice, couscous, crackers, flour tortillas, grits, pasta, white bread, and corn flake cereal. Some products are made with a mixture of whole grain and refined grain flours to help improve texture and taste but still retain some nutrients.

Any vegetable or any 100% vegetable juice is considered part of the vegetable group. This group is subdivided into different types of vegetables, based on nutrient content. The subgroups are:

- dark green vegetables—bok choy, broccoli, collard greens, dark green leafy lettuce, kale, mesclun, mustard greens, romaine lettuce, spinach, turnip greens, watercress
- red and orange vegetables—acorn squash, butternut squash, carrots, hubbard squash, pumpkin, red peppers, sweet potatoes, tomatoes, tomato juice
- beans and peas—black beans, black-eyed peas, chickpeas, kidney beans, lentils, navy beans, pinto beans, soy beans, split peas, white beans
- starchy vegetables—cassava, corn, green bananas, green or field peas, green lima beans, plantains, potatoes, taro, water chestnut
- other vegetables—artichokes, asparagus, avocado, bean sprouts, beets, Brussels sprouts, cabbage, cauliflower, celery, cucumbers, eggplant, green beans, green peppers, lettuce, mushrooms, okra, onions, parsnips, turnips, wax beans, zucchini

Fruits can be fresh, canned, frozen, or dried. One hundred percent fruit juice also counts as fruit. Virtually all fruit is included in this group, including citrus fruits, berries, melons, and common fruits such as apples, bananas, pears, and raisins (dried grapes).

Nonfat, low-fat, and whole milk all contain about the same amount of calcium, the most important mineral in milk. Nonfat and low-fat milk are the preferred choices in this group. Other foods in the milk group include yogurt, cheese, and desserts made with milk such as ice cream and pudding. When foods like ice cream, full-fat cheese, or sweetened yogurt are selected, the extra calories from fat and sugar should be subtracted from a person's daily discretionary calories (calories allotted for treat foods such as desserts). People who are lactose intolerant can choose lactose-reduced and lactose-free products. Cream cheese and butter contain only small amounts of calcium and are not counted as dairy servings.

The protein group includes meats, poultry, eggs, beans and peas (including soy products), nuts and seeds (including nut butters), and seafood. People who do not eat meat need to make sure they are getting adequate amounts of iron and other nutrients (e.g., vitamin B_{12}). The meat group contains several subgroups, including lean cuts, game meats, ground meats, deli meats, and organ meats. People should try to eat less red meat and more fish, poultry, and dried beans. Meat should be trimmed of all visible fat and baked, broiled, or grilled. If fat is added in cooking, it should be counted as an oil or in the discretionary calories.

Oils are liquid at room temperature, compared to fats, which are solid at room temperature. Oils are preferred because they contain less saturated fat and *trans* fat. Diets high in saturated fat and *trans* fat are associated with an increased risk of cardiovascular disease.

Oils come from plant sources and include olive oil, canola oil, corn oil, safflower oil, and oil blends. Fats come mainly from animal sources and include butter,

lard (pork fat), tallow (beef fat), and chicken fat. Stick margarine and shortening are made of vegetable oils that are treated to make them solid. This process, called hydrogenation, increases the amount of saturated fat and *trans* fats they contain, making them less desirable sources of fat. Palm and coconut oils, although liquid at room temperature, are not recommended because they are unusually high in saturated fat and *trans* fat. Avocados, nuts, olives, and some fish, such as salmon, are high in oils, but they contain omega-3s, which are beneficial to health.

Empty calories are calories derived from solid fats or added sugars that provide little-to-no nutritional value. Foods like desserts, soda pop, and fried foods may contain all or some empty calories. MyPlate acknowledges that occasional consumption of empty calories is okay, but these foods should be eaten in moderation and considered against daily caloric goals.

MyPlate recommends engaging in regular physical activity in addition to a person's normal daily routine. Adults are advised to do at least 2 hours and 30 minutes of moderate physical activity every week, or 75 minutes of vigorous activity every week. Children (ages 6–17) are recommended to participate in 60 minutes of activity every day. There are no specific recommendations for younger children, as they are generally regularly active.

Examples of moderate activities include:

- brisk walking
- hiking
- yard work and gardening
- dancing
- golfing without a golf cart
- easy bicycling
- light weight training

Vigorous activities include:

- running or jogging
- brisk or hard bicycling
- lap swimming
- aerobic exercising
- power walking
- many competitive sports (tennis, basketball, etc.)
- heavy yard work such as chopping wood
- heavy weight training

Healthy People 2020 is a set of national health objectives in the United States. Many of these objectives are related to improving health by changing and improving the typical "American" diet. The goals of Healthy People 2020 are to:

- attain high-quality, longer lives free of preventable disease, disability, injury, and premature death
- achieve health equity, eliminate disparities, and improve the health of all groups
- create social and physical environments that promote good health for all
- promote quality of life, healthy development, and healthy behaviors across all life stages

The National **Cholesterol** Education Program is another federal program intended to improve health. Begun in 1985, the goal of this program is to reduce illness and death from coronary heart disease by reducing the number of people in the United States with high cholesterol levels. The program promotes following a heart-healthy diet and provides information on how to lower cholesterol levels. Resources are available in several languages.

Registered dietitians (RDs) have the training and knowledge to accurately assess the nutritional adequacy of a individual's diet, especially if chronic disease is present. Doctors are also able to conduct a dietary assessment or provide general nutrition advice and/or diet therapy. Nurses and allied health professionals can reinforce good dietary choices and provide nutrition guidance for individuals in hospitals, long-term care facilities, or in community settings.

Medical nutrition therapy occurs when an individual uses dietary means to help recover or control a disease or condition. To maintain health in a individual with a nutrition-related illness, all healthcare team members and especially the individual being treated must commit to achieving optimum health through medical nutritional therapy. Prioritized goals are critical when developing the nutrition treatment plan. Continuous assessment is made by the individual and healthcare team members to evaluate the importance of these and other goals. Physicians must understand the dietary approaches an individual is using and reinforce this diet therapy when interacting with the individual. The position of the Academy of Nutrition and Dietetics is that medical nutritional therapy is effective in treating disease and preventing disease complications.

Purpose

The concept of diet quality in relation to health has changed over time. In the early 1900s, lack of refrigeration, frozen food technology, and reliable transportation meant that people ate what grew locally and what was available seasonally. At that time, nutrition scientists focused on preventing specific nutrient and calorie deficiencies. Today, most

WWW.BOOKBAZ.IR

KEY TERMS

Cholesterol—A waxy substance made by the liver and also acquired through diet. High levels in the blood may increase the risk of cardiovascular disease.

Registered dietitian (RD)—A health professional who has a bachelor's degree, specializing in foods and nutrition, and in addition, undergoes a period of practical training in a hospital or community setting. Many dietitians further their knowledge by pursuing master's or doctoral degrees. The title "registered dietitian" is protected by law so that only qualified practitioners who have met education qualifications can use that title.

people in developed countries have access to a large quantity and variety of foods. Nutrition researchers have shifted their focus to exploring the relationships among diet, chronic disease, longevity, and quality of life.

Well-nourished people have more energy, are more resistant to disease, and are better able to tolerate treatments and to recover from acute illnesses, surgery, and **trauma**. Consumption of a wide variety of foods, with appropriate amounts of protein, carbohydrate, fat, vitamins, and **minerals**, forms the basis of a healthy diet. However, many acute and chronic conditions are related to inadequate dietary intake. Obesity, a major **public health** concern, and many of the leading causes of death in the United States, including coronary heart disease, stroke, type 2 diabetes mellitus, and some cancers, are at least partially attributable to poor diet and excess alcohol consumption. Diet education has become a focus of public health outreach programs.

Dietary guidelines

Definition

The *Dietary Guidelines for Americans* are the foundation of the national **nutrition** policy for the United States. They are designed to help Americans make food choices that promote health and reduce the risk of disease. The guidelines are published jointly by the U.S. Department of Agriculture (USDA) and the U.S. Department of Health and Human Services (HHS). The first set of guidelines was published as *Nutrition and Your Health: Dietary Guidelines for*

Americans in 1980. Since then, an advisory committee has been appointed to review and revise the guidelines every five years based on the latest research in nutrition and health.

Description

Early dietary advice in the United States

The first half of the twentieth century was a period of enormous growth in nutrition knowledge. The primary goal of nutrition advice at this time was to help people select foods to meet their energy (calorie) needs and prevent diseases caused by nutritional deficiencies. During the Great Depression of the 1930s, many people had little money to buy food. They needed to know how to select an adequate diet with few resources. In response to this need, the USDA produced a set of meal plans that were affordable for families of various incomes. To this day, a food guide for low-income families—the Thrifty Food Plan—is issued regularly by the USDA and used to determine allotments in the Supplemental Nutrition Assistance Program (SNAP), formerly called food stamps. In addition to meal plans, the USDA develops food guides as tools to help people select healthful **diets**. These food guides have changed over the years, based on the most recent research and information available.

Food guides versus dietary guidelines

Food guides are practical tools that people can use to select a healthful diet. Food guide recommendations, such as how much protein to eat daily, are based on dietary guidelines that are overall recommendations for well-rounded diets. For example, the *Dietary Guidelines for Americans* issued in 2010 emphasized consuming fewer calories and included the recommendation that Americans "make half [their] plate fruits and vegetables." The current USDA food guide, based on the 2010 dietary guidelines, is called MyPlate. MyPlate was issued in June 2011. It replaced various versions of the food pyramid that had been used for 19 years. MyPlate simplifies food choice recommendations and shows them in a clear graphic of a plate divided into 30% grains, 30% vegetables, 20% fruits, and 20% protein. A smaller circle separate from the plate represents dairy products. Supplemental MyPlate recommendations include eating smaller portions, choosing whole grains over refined grains (e.g., brown rice instead of white rice), choosing dairy products made with skim or low-fat milk, and reducing sugar and salt intake. Adjustments are made for special groups, such as children under two and pregnant or **breastfeeding** women.

KEY TERMS

Type 2 diabetes—A type of diabetes that usually develops later in life. The pancreas either does not make enough insulin or cells become insulin resistant and do not use insulin efficiently.

Evolution of the dietary guidelines

During the 1970s, scientists began identifying links between people's eating habits and their risk for developing chronic diseases, such as **heart disease**, type 2 diabetes, and cancer. They realized that a healthful diet was important not only to prevent diseases caused by nutrient deficiencies but also because it could play a role in decreasing the risk of developing chronic diseases. Since heart disease, diabetes, and cancer were, and still are, major causes of death and disability in the United States, there was a need to help Americans select diets that promoted good health. It later became evident that a healthful diet is one of the most affordable and effective modes of treatment and management of chronic diseases.

The first major step in federal dietary guidance was the 1977 publication of *Dietary Goals for the United States* by the Senate Select Committee on Nutrition and Human Needs. The publication recommended an increased intake of carbohydrates and a reduced intake of fat, saturated fat, **cholesterol**, **sodium** (salt), and sugar. At the time, there was heated debate among nutrition scientists about these recommendations. Some nutritionists believed that not enough was known about effects of diet on health to make suggestions as specific as those given.

In 1980, the first edition of *Dietary Guidelines for Americans* was released by the USDA and HHS. The seven guidelines were:

1. Eat a variety of foods.
2. Maintain ideal weight.
3. Avoid too much fat, saturated fat, and cholesterol.
4. Eat foods with adequate starch and fiber.
5. Avoid too much sugar.
6. Avoid too much sodium (salt).
7. Drink alcohol only in moderation.

The second edition, released in 1985, made a few changes, but kept most of the guidelines intact. Two exceptions were the weight guideline, which was changed to "maintain desirable weight" and the last

WWW.BOOKBAZ.IR

guideline, in which "alcohol" was changed to "alcoholic beverages."

Following publication of the second edition of the *Dietary Guidelines*, two influential reports concerning diet and health were issued. The *Surgeon General's Report on Nutrition and Health* was published in 1988, and the National Research Council's report *Diet and Health—Implications for Reducing Chronic Disease Risk* was published in 1989. These two reports supported the goal of the guidelines to promote eating habits to help people stay healthy. In 1990, the third edition of the guidelines took a more positive tone than previous editions, using phrases such as "choose a diet," or "use . . . only in moderation," rather than "avoid too much. . ." This was seen as a positive step by many nutrition educators.

The fourth edition was the first to include the Food Guide Pyramid, which had been introduced in 1992. It also was the first edition to address vegetarian diets and the recently introduced "Nutrition Facts" panel for food labels. The fifth edition, issued in 2000, expanded the number of guidelines to ten and organized them into three messages: "Aim for Fitness, Build a Healthy Base, and Choose Sensibly" (ABC).

With the sixth edition in 2005, a redesigned food pyramid called MyPyramid was introduced. MyPyramid was intended to help Americans become more aware of what they eat and their nutrient needs. It was designed to help people learn how to eat a healthy diet, live an active lifestyle, and maintain or gradually move in the direction of a healthy weight that would reduce the risk of weight-related diseases. Unlike earlier diet and nutrition guides, MyPyramid personalized dietary recommendations based on the individual's height, weight, age, gender, activity level, and weight goals. MyPyramid was not well received by many nutrition educators who felt the graphic was confusing and the advice so overwhelmingly detailed and specific that it would discourage the average person. MyPyramid was replaced in June 2011 with the simpler MyPlate graphic and guidelines.

The 2010 Dietary Guidelines for Americans

On January 31, 2011, the USDA and HHS announced the 2010 *Dietary Guidelines for Americans*. The 2010 release was the seventh edition of the guidelines and was developed specifically to help combat the increasing **obesity** problem in the United States. It focused on providing recommendations that were simple to understand and easy for busy people to put into practice in their daily lives.

Some of the guidelines from the 2010 directive include:

- Enjoy your food, but eat less.
- Avoid oversized portions.
- Make half your plate fruits and vegetables.
- Drink water instead of sugary drinks.
- Switch to fat-free or low-fat milk.

The 2010 guidelines also include a variety of other recommendations. The two overarching themes of the recommendations are to maintain calorie balance over time to achieve and sustain a healthy weight, and to focus on consuming nutrient-dense foods and beverages. The full text of the recommendations, as well as a variety of interactive tools and other helpful nutrition information can be found at http://www.cnpp.usda.gov/dietaryguidelines.htm.

Linda Benjamin Bobroff
REVISED BY TISH DAVIDSON, AM

Diets

Definition

Humans may alter their usual eating habits for many reasons, including weight loss, disease prevention or treatment, removing toxins from the body, or to achieve a general improvement in physical and mental health. Others adopt special diets for religious reasons. In the case of some vegetarians and vegans, dietary changes are made out of ethical concerns for the rights of animals.

Purpose

People who are moderately to severely overweight can derive substantial health benefits from a weight-loss diet. A weight reduction of just 10–20 lb (4.5–9) can result in reduced **cholesterol** levels and lower blood pressure. Weight-related health problems include **heart disease**, diabetes, high blood pressure, and high levels of blood sugar and cholesterol.

In individuals who are not overweight, dietary changes also may be useful in the prevention or treatment of a range of ailments including acquired immuno deficiency syndrome (**AIDS**), cancer, **osteoporosis**, inflammatory bowel disease, chronic pulmonary disease, renal disease, **Parkinson's disease**, seizure disorders, and **food allergies** and intolerances.

Description

Origins

The practice of altering diet for special reasons has existed since antiquity. For example, Judaism has included numerous dietary restrictions for thousands of years. One ancient Jewish sect, the Essenes, is said to have developed a primitive **detoxification** diet aimed at preparing the bodies, minds, and spirits of its members for the coming of a "messiah" who would deliver them from their Roman captors. Preventive and therapeutic diets became popular during the late twentieth century. Books promoting the latest dietary plan continue to make the bestseller lists, although not all of the information given is considered authoritative.

The idea of a healthful diet is to provide all of the calories and nutrients needed by the body for optimal performance, at the same time ensuring that neither nutritional deficiencies nor excesses occur. Diet plans that claim to accomplish those objectives are so numerous they are virtually uncountable. These diets employ a variety of approaches, including the following:

- Fixed-menu: Offers little choice to the dieter. Specifies exactly which foods will be consumed.

USDA food intake recommendations

Daily caloric intake	1,000	1,200	1,400	1,600	1,800	2,000	2,200	2,400	2,600	2,800	3,000	3,200
Fruits	1 cup	1 cup	1.5 cups	1.5 cups	1.5 cups	2 cups	2 cups	2 cups	2 cups	2.5 cups	2.5 cups	2.5 cups
Vegetables	1 cup	1.5 cups	1.5 cups	2 cups	2.5 cups	2.5 cups	3 cups	3 cups	3.5 cups	3.5 cups	4 cups	4 cups
Grains	3 oz-eq	4 oz-eq	5 oz-eq	5 oz-eq	6 oz-eq	6 oz-eq	7 oz-eq	8 oz-eq	9 oz-eq	10 oz-eq	10 oz-eq	10 oz-eq

(Table by PreMediaGlobal. © Cengage Learning®.)

WWW.BOOKBAZ.IR

Easy to follow, but may be considered boring to some dieters.

- Formula: Replaces some or all meals with a nutritionally balanced liquid formula or powder.
- Exchange-type: Allows the dieter to choose between selected foods from each food group.
- Flexible: Doesn't concern itself with the overall diet, simply with one aspect such as fat or energy.

Diets also may be classified according to the types of foods they allow. For example, an omnivorous diet consists of both animal and plant foods, whereas a lacto-ovo-vegetarian diet permits no animal flesh, but includes eggs, milk, and dairy products. A vegan diet is a stricter form of **vegetarianism** in which eggs, cheese, and other milk products are prohibited.

A third way of classifying diets is according to their purpose: religious, weight-loss, detoxification, lifestyle-related, or aimed at prevention or treatment of a specific disease.

Precautions

Dieters should be cautious about plans that severely restrict the size of food portions, or that eliminate entire food groups from the diet. It is highly probable that they will become discouraged and drop out of such programs. The best diet is one that can be maintained indefinitely without ill effects, that offers sufficient variety and balance to provide everything needed for good health, and that is considerate of personal food preferences. Many controversies have arisen in the past over the benefits and risks of high-protein, low carbohydrate diets such as the Atkins diet. Most physician groups and health organizations have spoken out negatively against the program. In 2003, these statements were largely supported. Though clinical trials showed that these types of diets worked in lowering weight without raising cholesterol for the short-term, many of the participants gained a percentage of the weight back after only one year. A physician group also spoke out about high protein diets' dangers for people with decreased kidney function and the risk of bone loss due to decreased **calcium** intake.

Low-fat diets are not recommended for children under the age of two. Young children need extra fat to maintain their active, growing bodies. Fat intake may be gradually reduced between the ages of two and five, after which it should be limited to a maximum of 30% of total calories through adulthood. Saturated fat should be restricted to no more than 10% of total calories.

Weight-loss dieters should be wary of the "yo-yo" effect that occurs when numerous attempts are made to reduce weight using high-risk, quick-fix diets. This continued "cycling" between weight loss and weight gain can slow the basal metabolic rate and can sometimes lead to **eating disorders**. The dieter may become discouraged and frustrated by this success/failure cycle. The end result of yo-yo dieting is that it becomes more difficult to maintain a healthy weight.

Caution also should be exercised about weight loss diets that require continued purchases of special prepackaged foods. Not only do these tend to be costly and over-processed, they also may prevent dieters from learning the food-selection and preparation skills essential to maintenance of weight loss. Further, dieters should consider whether they want to carry these special foods to work, restaurants, or homes of friends.

Concern has been expressed about weight-loss diet plans that do not include **exercise**, considered essential to long-term weight management. Some diets and supplements may be inadvisable for patients with special conditions or situations. In fact, use of the weight loss supplement ephedra was found to cause serious conditions such as **heart attack** and **stroke**. In 2003, the U.S. Food and Drug Administration (FDA) was considering controlling or banning the supplement. In short, most physician organizations see fad diets as distracting from learning how to achieve weight control over the long term through healthy lifestyle changes such as eating smaller, more balanced meals and exercising regularly.

Certain fad diets purporting to be official diets of groups such as the American Heart Association and the Mayo Clinic are in no way endorsed by those institutions. People thinking of starting such a diet should check with the institution to ensure its name has not been misappropriated by an unscrupulous practitioner.

Side effects

A wide range of side effects (some quite serious) can result from special diets, especially those that are nutritionally unbalanced. Further problems can arise if the dieter is taking high doses of dietary supplements. Food is essential to life, and improper **nutrition** can result in serious illness or death.

Research and general acceptance

It is agreed among traditional and complementary practitioners that many patients could substantially benefit from improved eating habits. Specialized

diets have proved effective against a wide variety of conditions and diseases. However, dozens of unproved but widely publicized fad diets emerge each year, prompting widespread concerns about their usefulness, cost to the consumer, and their safety.

DiGeorge syndrome

Definition

DiGeorge syndrome (also called 22q11 deletion syndrome, congenital thymic hypoplasia, or third and fourth pharyngeal pouch syndrome) is a birth defect that is caused by an abnormality in chromosome 22 and affects the baby's immune system. The disorder is marked by absence or underdevelopment of the thymus and parathyroid glands. It is named for Angelo DiGeorge, the pediatrician who first described it in 1965. Some researchers prefer to call it DiGeorge anomaly, or DGA, rather than DiGeorge syndrome, on the grounds that the defects associated with the disorder represent the failure of a part of the human embryo to develop normally rather than a collection of symptoms caused by a single disease.

Description

The prevalence of DiGeorge syndrome is debated; the estimates range from 1:4,000 to 1:6,395. Because the symptoms caused by the chromosomal abnormality vary somewhat from patient to patient, the syndrome probably occurs much more often than was previously thought. DiGeorge syndrome is sometimes described as one of the "CATCH 22" disorders, so named because of their characteristics—cardiac defects, abnormal facial features, thymus underdevelopment, **cleft palate**, and hypocalcemia—caused by a deletion of several genes in chromosome 22. The specific facial features associated with DiGeorge syndrome include low-set ears, wide-set eyes, a small jaw, and a short groove in the upper lip. The male/female ratio is 1:1. The syndrome appears to be equally common in all racial and ethnic groups.

Causes and symptoms

DiGeorge syndrome is caused either by inheritance of a defective chromosome 22 or by a new defect in chromosome 22 in the fetus. The type of defect that is involved is called deletion. A deletion occurs when the genetic material in the chromosomes does not recombine properly during the formation of sperm or egg cells. The deletion means that several genes from chromosome 22 are missing in DiGeorge syndrome patients. Although efforts have been made in the early 2000s to identify individual candidate genes for DGA, it appears that a combination of several genes in the deleted area is responsible for the disorder. Detailed genetic mapping of chromosome 22 has, however, identified a so-called DiGeorge critical region (DGCR), which has been completely sequenced.

According to a 1999 study, 6% of children with DiGeorge syndrome inherited the deletion from a parent, while 94% had a new deletion. Other conditions that are associated with DiGeorge syndrome are diabetes (a condition where the pancreas no longer produces enough insulin) in the mother and **fetal alcohol syndrome** (a pattern of **birth defects**, and learning and behavioral problems affecting individuals whose mothers consumed alcohol during **pregnancy**). Other chromosomal abnormalities that have been found in patients diagnosed with DGA include deletions on chromosomes 10p13, 17p13, and 18q21.

The loss of the genes in the deleted material means that the baby's third and fourth pharyngeal pouches fail to develop normally during the twelfth week of pregnancy. This developmental failure results in a completely or partially absent thymus gland and parathyroid glands. In addition, 74% of fetuses with DiGeorge syndrome have severe heart defects. The child is born with a defective immune system and an abnormally low level of **calcium** in the blood. Some children with DGA are also born with malformations of the genitals or urinary tract.

WWW.BOOKBAZ.IR

These defects usually become apparent within 48 hours of birth. The infant's heart defects may lead to **heart failure**, or there may be seizures and other evidence of a low level of calcium in the blood (**hypocalcemia**).

DiGeorge syndrome is also associated with an increased risk of **autoimmune disorders**. Cases have been reported of DGA in association with Graves' disease, immune thrombocytopenic purpura, juvenile **rheumatoid arthritis**, and severe **eczema**.

Diagnosis

Diagnosis of DiGeorge syndrome can be made by **ultrasound** examination around the eighteenth week of pregnancy, when abnormalities in the development of the heart or the palate can be detected. Another technique that is used to diagnose the syndrome before birth is called fluorescence in situ hybridization, or FISH. This technique uses DNA probes from the DiGeorge region on chromosome 22. FISH can be performed on cell samples obtained by **amniocentesis** as early as the fourteenth week of pregnancy. It confirms about 95% of cases of DiGeorge syndrome.

If the mother has not had prenatal testing, the diagnosis of DiGeorge syndrome is sometimes suggested by the child's facial features at birth. In other cases, the doctor makes the diagnosis during heart surgery when he or she notices the absence or abnormal location of the thymus gland. The diagnosis can be confirmed by blood tests for calcium, phosphorus, and parathyroid hormone levels, and by the sheep cell test for immune function.

Treatment

Hypocalcemia

Hypocalcemia in DiGeorge patients is unusually difficult to treat. Infants are usually given calcium and **vitamin D** by mouth. Severe cases have been treated by transplantation of fetal thymus tissue or bone marrow.

Heart defects

Infants with life-threatening heart defects are treated surgically.

Defective immune function

Children with DiGeorge syndrome should be kept on low-phosphorus **diets** and kept away from crowds or other sources of infection. They should not be immunized with vaccines made from live viruses or given **corticosteroids**.

KEY TERMS

Deletion—A genetic abnormality in which a segment of a chromosome is lost. DiGeorge syndrome is caused by a deletion on human chromosome 22.

Fetal alcohol syndrome—A cluster of birth defects that includes abnormal facial features and intellectual disabilities (ID), caused by the mother's consumption of alcoholic beverages during pregnancy.

Fluorescence in situ hybridization (FISH)—A technique for diagnosing DiGeorge syndrome before birth by analyzing cells obtained by amniocentesis with DNA probes. FISH is about 95% accurate.

Hypocalcemia—An abnormally low level of calcium in the blood.

Hypoplasia—A deficiency or underdevelopment of a tissue or body structure.

T cells—A type of white blood cell produced in the thymus gland. T cells are an important part of the immune system. Infants born with an underdeveloped or absent thymus do not have a normal level of T cells in their blood.

Prognosis

The prognosis is variable; many infants with DiGeorge syndrome die from overwhelming infection, seizures, or heart failure within the first year. One study of a series of 558 patients reported 8% mortality within six months of birth, with heart defects accounting for all but one of the deaths. Infections resulting from severe immune deficiency are the second most common cause of death in patients with DGA. Advances in heart surgery indicate that the prognosis is most closely linked to the severity of the heart defects and the partial presence of the thymus gland. In most children who survive, the number of T cells, a type of white blood cell, in the blood rises spontaneously as they mature. Survivors are likely to be mentally impaired and have other developmental difficulties, including seizures or other psychiatric and neurological problems in later life.

Prevention

Genetic counseling is recommended for parents of children with DiGeorge syndrome because the

disorder can be detected prior to birth. Although most children with DiGeorge syndrome did not inherit the chromosome deletion from their parents, they have a 50% chance of passing the deletion on to their own children.

Because of the association between DiGeorge syndrome and fetal alcohol syndrome, pregnant women should avoid drinking alcoholic beverages.

Rebecca J. Frey, PhD

Digital rectal examination

Definition

The digital **rectal examination** (DRE) is a routine part of the **physical examination** and includes manual examination of the rectum, anus and, in men, the prostate.

KEY TERMS

Fissure—Any cleft or groove, normal or otherwise, especially a deep fold in the anus.

Lesion—Any pathological or traumatic discontinuity of tissues or loss of function of a part.

Palpation—A simple technique in which a doctor presses lightly on the surface of the body to feel the organs or tissues underneath.

Peritonitis—Inflammation of the peritoneum. It may be accompanied by abdominal pain and tenderness, constipation, vomiting and moderate fever.

Polyp—Growth, usually benign, protruding from a mucous membrane.

Rectal prolapse—Protrusion of the rectal mucous membrane through the anus.

Skin tag—A small outgrowth of skin tissue that may be smooth or irregular, flesh-colored and benign.

Purpose

The purpose of the digital rectal examination is to identify lesions within the rectum and the prostate. It is the most widely used and oldest technique for the detection of **prostate cancer** and is used in screening for **colon cancer** and for the detection of **rectal polyps**.

Description

Usually the patient is positioned on the left side with the knees close to the chest. Sometimes the patient is asked to stand up and lean over the examination table. For women, sometimes this examination is part of the routine gynecological exam, and it may be done in a different manner.

During the examination, the health care practitioner examines the anus and the surrounding skin for **hemorrhoids**, tags, fissures and abscesses. After lubricating the gloved finger and anus, the examiner gently slides the finger into the anus and follows the contours of the rectum. The examiner notes the tone of the anus and feels the walls and the edges for texture, tenderness and masses as far as the examining finger can reach. The examiner evaluates the prostate for nodules and tenderness. Stool on the finger should be examined for blood, color, texture and tested for fecal occult blood.

The examination takes less than two minutes and can be uncomfortable when the patient is not relaxed

WWW.BOOKBAZ.IR

or is anxious. Occasionally, when the DRE is performed on a man the penis may become erect. A gentle reminder and reassurance helps to relieve the embarrassment associated with the unexpected erection.

Preparation

The patient must be carefully positioned and the doctor should take care to explain the examination to the patient and to explain to the patient what to expect. The digital rectal examination may be uncomfortable and embarrassing. Much of the discomfort can be reduced by an understanding, unhurried and gentle examiner.

Precautions

When there are infections of the anus and of the rectum, the digital rectal examination should not be performed. Manipulation of the anal and rectal tissues increases the risk of infection and of bleeding.

Results

In the normal anus and rectum, there are no hemorrhoids or bleeding about the anus. The anal tone is not loose. The rectum is smooth and non-tender. No masses should be palpated, or felt.

The digital rectal examination is helpful in identifying areas of **peritonitis** or tender areas that can be felt through the wall of the rectum. It is used to identify perineal disease or deformity, abnormal location of the anus, **rectal prolapse** and atrophy of the gluteal muscle. Digital examination can detect a stenosis (or narrowing) of the anal canal, assess the tone and strength of the anal muscles or detect the presence of a rectal mass or fecal impaction.

Any masses, including hard stool, blood or tenderness is considered abnormal. Cancer masses may be flattened, nodular, cauliflower-like or ring-shaped. Polyps can be felt, but must be visualized using **anoscopy** or flexible **sigmoidoscopy** to be distinguished from other lesions, such as internal hemorrhoids or malignant growths. Hard masses of feces may be felt and may be removed.

Aftercare

Aftercare of the digital rectal examination is minimal. It requires removal of the lubricating jelly residue from around the anus. The lubricating jelly dissolves easily in water and may be washed off in bathing after the examination. It can be removed with toilet paper immediately after the examination.

Digoxin

Definition

Digitalis occurs naturally in the foxglove plant, (*Digitalis purpurea*), and was used for centuries to treat **heart disease**. Currently, its active ingredient, digoxin (Lanoxin), is manufactured synthetically.

Purpose

Digoxin increases the strength and speed of heart muscle contractions and is used to treat **congestive heart failure**, where the heart is unable to pump all of the blood it receives.

Digoxin is used to slow the heart rate and improve the efficiency of the ventricles (main pumping chambers) when there are rapid or irregular heart beats, like **atrial flutter** or fibrillation.

The drug is also used to strengthen the heart in some cases of **shock**, like from **heart attack** or **sepsis** (overwhelming infection).

Description

Digoxin is available in tablet, capsule, liquid, and injectable forms.

Recommended dosage

The dose of digoxin is individualized for each patient. Physicians can tailor the dose based on patient response and laboratory measures of blood levels of the drug.

Digitalis purpurea. *(Photo Researchers, Inc.)*

Precautions

This drug should be taken exactly as directed.

Digoxin is used with caution, or not given, in patients who have a number of serious heart diseases, like recent heart attack, subaortic ventricular stenosis and second or third degree **heart block**.

The elderly, newborns, and people with reduced kidney function are more sensitive to the effects of digoxin,

There is a narrow therapeutic range between effective and toxic doses of digoxin.

People taking digoxin should regularly check their pulse rate and rhythm; changes can signify side effects and should be reported to treating physicians.

Digitalis drugs are responsible for many accidental poisonings in children. Keep this medicine out of the reach of children.

Be alert to the signs and symptoms of digoxin overdose. If any of these signs occur, check with your physician soon:

- loss of appetite
- nausea
- vomiting
- pain in the lower stomach
- diarrhea
- tiredness or weakness
- extremely slow or irregular heartbeat (or fast heartbeat in children)
- blurred vision or other vision changes
- drowsiness
- confusion, unusual fatigue or depression
- headache
- fainting

Before taking digoxin, people with any of the following the medical problems should make sure their physicians are aware of their conditions:

- heart disease
- heart rhythm problems
- severe lung disease
- kidney disease
- liver disease
- thyroid disease

Side effects

In therapeutic doses, side effects are rare with digoxin. If skin rash, **hives**, or any other unusual or troublesome symptoms occur, check with a physician.

Interactions

Many drugs, foods and herbs can increase or decrease the effectiveness of digoxin. For example:

- Taking digoxin with other heart medicines or stimulant drugs like diet pills, amphetamines, or ephedra can increase the risk of heart rhythm problems.
- Calcium channel blocking drugs, like Procardia and Norvasc, used to treat high blood pressure, may cause higher than usual levels of digoxin.
- Many diuretics, like Hydrodiuril, cause the body to lose potassium and increase the risk of side effects from digoxin.
- Potassium supplements, like K-Dur, used to replentish potassium supplies in patients taking diuretics, can increase the risk of digoxin toxicity.

WWW.BOOKBAZ.IR

- Cholesterol-lowering drugs like Lipitor may increase digoxin levels in the blood.
- Cholestyramine, Questran, may reduce the absorption of digoxin. To reduce this possible problem, digoxin should be taken several hours before or after taking these medicines.
- Anti-diarrhea medicines may decrease the absorption of digoxin.
- St. Johns wort and natural licorice can decrease the effect of digoxin.

Check with a pharmacist on the possible interactions of all of the medications you take with digoxin.

James Waun, MD, RPh

Digoxin *see* **Digitalis drugs; Antiarrhythmic drugs**

Dilatation and curettage

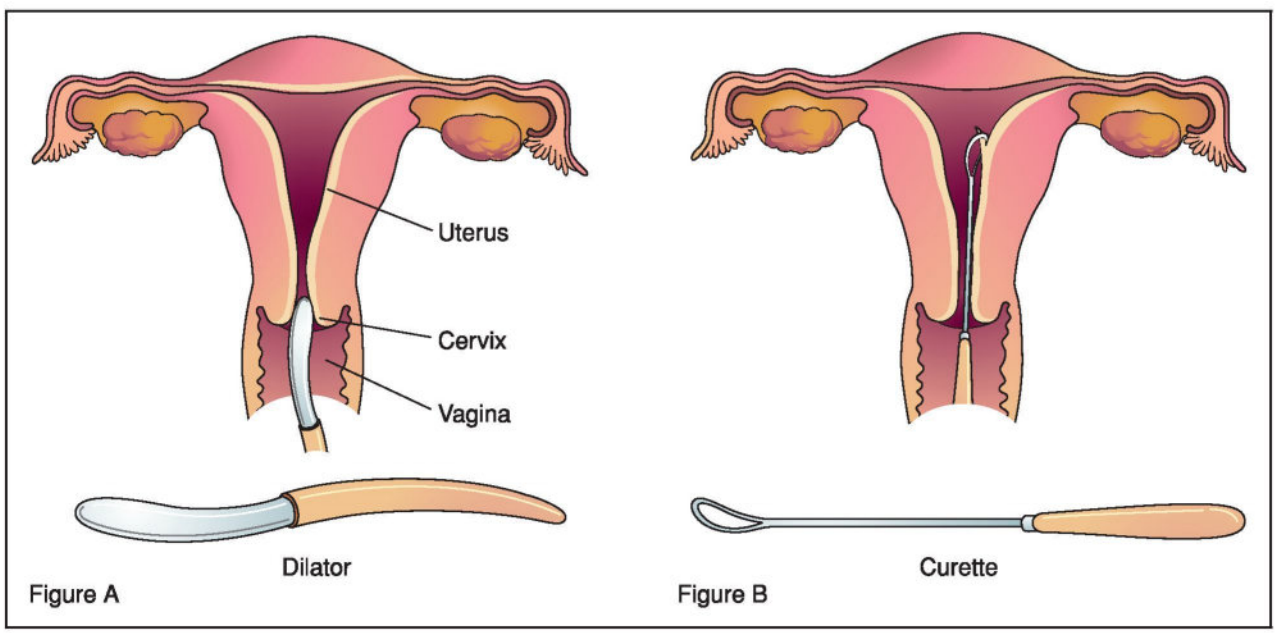
Definition

Dilatation and curettage (D & C) is a gynecological procedure in which the cervix is dilated (expanded) and the lining of the uterus (endometrium) is scraped away.

Purpose

D & C is used to diagnose and treat heavy or irregular bleeding from the uterus. Possible reasons for abnormal uterine bleeding include:

- Hormonal imbalance. Often women with abnormal bleeding are first treated with hormones in an attempt to normalize bleeding. D & C may be used to determine the cause of bleeding if hormone treatment is ineffective.
- Endometrial polyps. Polyps are benign growths that may protrude from the uterus by a stem or stalk, usually to the endometrium or cervix. D & C may be used to diagnose polyps or to remove them.
- Uterine fibroids. Also called leiomyomas, fibroids are benign growths in the smooth muscle of the uterus. Abnormal bleeding is often the only symptom of fibroids. D & C is often used to diagnose fibroids and may be used to scrape away small tumors; additional surgery may be needed to remove more extensive growths.
- Endometrial hyperplasia (EH). EH is a condition where the endometrium grows excessively, becoming too thick and causing abnormal bleeding. Tissue samples procured during D & C can be assessed for early signs of cancer.
- Cancer. D & C may be used to obtain tissue for microscopic evaluation to rule out cancer. Women



Dilatation and curettage (D & C) is used primarily to diagnose and treat heavy menstrual bleeding and to diagnose endometrial polyps, uterine fibroids, uterine cancer and cervical cancer. *(Illustration by Electronic Illustrators Group. © Cengage Learning®.)*

KEY TERMS

Endometrial polyps—Growths in the lining of the uterus (endometrium) that may cause bleeding and can develop into cancer.

Epidural anesthesia—A type of anesthesia that is injected into the epidural space of the spinal cord to numb the nerves leading to the lower half of the body.

Uterine fibroid—A non-cancerous tumor of the uterus that can range from the size of a pea to the size of a grapefruit. Small fibroids require no treatment, but those causing serious symptoms may need to be removed.

over the age of 40 are at an increased risk of developing endometrial cancer.

- Miscarriage, incomplete abortion, or childbirth. Abnormal bleeding may result if some of the products of pregnancy remain in the uterus after a miscarriage or induced abortion, or if parts of the placenta are not expelled naturally after childbirth. These retained products can be scraped out by D & C.

Description

D & C is generally performed by an obstetrician/gynecologist, a medical doctor who has completed specialized training in the areas of women's general health, **pregnancy**, labor and **childbirth**, prenatal testing, and genetics. Samples of the uterine lining may be sent to a pathologist for analysis. A pathologist is a medical doctor who has completed specialized training in the diagnosis of diseases from microscopic analysis of cells and tissues.

The health of the patient and the type of anesthesia used determines where a D & C is performed. The procedure is generally done in a hospital or an outpatient setting.

D & C is usually performed under general **anesthesia**, although local or epidural anesthesia can also be used. Local anesthesia lessens risk and costs, but the woman will feel cramping during the procedure. The type of anesthesia used often depends on the reason for the D & C.

During the procedure, which takes only minutes to perform, the doctor inserts an instrument called a speculum to hold open the vaginal walls, and then stretches the opening of the uterus (the cervix) by inserting a series of tapering rods, each thicker than the previous one, or by using other specialized instruments. This process of opening the cervix is called dilation.

Once the cervix is dilated, the physician inserts a spoon-shaped surgical device called a curette into the uterus. The curette is used to scrape away the uterine lining. One or more small tissue samples from the lining of the uterus or the cervical canal are sent for analysis by microscope to check for abnormal cells.

Although simpler, less expensive techniques such as a vacuum aspiration are quickly replacing the D & C as a diagnostic method, it is still often used to diagnose and treat a number of conditions.

Preparation

If general anesthesia will be used, the patient will be instructed to refrain from eating and drinking for at least eight hours before the procedure. The doctor may order blood and/or urine tests to scan for certain abnormalities. Because opening the cervix can be painful, sedatives may be given before the procedure begins. Deep breathing and other relaxation techniques may help ease cramping during cervical dilation.

Aftercare

A woman who has had a D & C performed in a hospital can usually go home the same day or the next day. Many women experience backache and mild cramps after the procedure, and may pass small **blood clots** for a day or so. Vaginal staining or bleeding may continue for several weeks.

Most women can resume normal activities almost immediately. Patients should avoid sexual intercourse, douching, and tampon use for at least two weeks to prevent infection while the cervix is closing and to allow the endometrium to heal completely.

Risks

The primary risk after the procedure is infection. A woman should report to her doctor if she experiences any of the following symptoms:

- fever
- heavy bleeding
- severe cramps
- foul-smelling vaginal discharge

WWW.BOOKBAZ.IR

D & C is a surgical operation that has certain risks associated with general anesthesia such as pulmonary aspiration and failed intubation. Rare complications include perforation of the uterus (which usually heals on its own) or puncture of the bowel or bladder (which requires further surgery to repair).

Extensive scarring of the uterus may occur after over-aggressive scraping during D & C, leading to a condition called Asherman's syndrome. The major symptoms of Asherman's syndrome are light or absent menstrual periods, **infertility**, and recurrent miscarriages. Scar tissue can be removed with surgery in most women, although approximately 20–30% of women will remain infertile after treatment.

Results

Removal of the uterine lining will normally cause no side effects, and may be beneficial if the lining has thickened so much that it causes heavy periods. The uterine lining soon grows again normally, as part of the menstrual cycle.

D & C has been associated with a 4–10% rate of postoperative complications.

Alternatives

There are a number of alternatives to D & C, depending on the reason for doing the procedure. Examples of procedures that allow doctors alternative ways of evaluating, sampling, or treating disorders of the inner lining of the uterus include:

- Expectant management of spontaneous abortion. D & C is the most commonly used method of treatment for incomplete abortion; one study showed that more than 90% of women who visited hospital emergency rooms for incomplete spontaneous abortion were treated by D & C. Recent studies, however, have shown that expectant management (i.e., no active intervention) is a viable option for women who do not wish to undergo surgery and who are in otherwise good health. Up to 72% of women indicated that expectant management of incomplete abortion was preferable to medical or surgical intervention.
- Endometrial biopsy. This procedure is similar to D & C in that a curette is used to obtain a sample of endometrial tissue. Little or no cervical dilation is necessary, however, because the curette used in endometrial biopsy is narrower. The cervix is numbed with a local anesthetic, but the patient will still experience cramping.
- Vacuum scraping. A thin plastic tube attached to a suction machine is passed through the cervix and scraped along the endometrium. Vacuum scraping has been shown to have similar success in diagnosing uterine cancer as D & C. Local anesthesia is also used for this procedure.
- Hysteroscopy. A thin telescope called a hysteroscope is inserted through the cervix and used to view the inside of the uterus after it has been expanded with a liquid or gas. The view afforded by the hysteroscope can help to diagnose abnormal growths, accumulation of scar tissue, or other conditions.
- Hysterectomy. A total hysterectomy permanently removes the uterus and cervix. This procedure is generally recommended only if a woman no longer desires to have children and no other forms of treatment have been successful. Most hysterectomies are done to treat uterine fibroids and endometriosis (a condition in which the endometrium grows outside of the uterus).

Diphtheria

Definition

Diphtheria is a potentially fatal, contagious disease that usually involves the nose, throat, and air passages, but may also infect the skin. Its most striking feature is the formation of a grayish membrane covering the tonsils and upper part of the throat.

Demographics

Before 1920 when the diphtheria toxoid was introduced, diphtheria was a major childhood killer, with 200,000 cases reported annually in the United States. In the twenty first century, diphtheria is rare and sporadic in the developed world because of widespread immunization. In countries that do not have routine immunization against this infection, periodic outbreaks occur. The largest recent outbreak occurred in the countries comprising the former Soviet Union and the Baltic States. From 1990–1995, 157,000 cases and 5,000 deaths were reported in this region, accounting for more than 80% of all diphtheria cases reported during those years. Other, smaller outbreaks have been reported in sub-Saharan Africa, India, and France. Like many other upper respiratory diseases, diphtheria is most likely to occur during the cold months. Individuals who have not been immunized may get diphtheria at any age; mortality rates are highest in those under five years or over 40 years of age.

Description

Diphtheria is spread most often by droplets from the coughing or sneezing of an infected person or carrier. The incubation period is two to seven days, with an average of three days. It is vital to seek medical help at once when diphtheria is suspected, because treatment requires emergency measures for adults as well as children.

Risk factors for developing diphtheria include:

- failure to immunize or incomplete immunization
- living in crowded, unhygienic conditions
- having a compromised immune system
- traveling to developing regions of the world where diphtheria is more common

Causes and symptoms

The symptoms of diphtheria are caused by toxins produced by the diphtheria bacillus, *Corynebacterium diphtheriae* (from the Greek for "rubber membrane"). In fact, toxin production is related to infections of the bacillus itself with a particular bacterial virus called a phage (from bacteriophage; a virus that infects bacteria). The infection destroys healthy tissue in the upper area of the throat around the tonsils, or in open **wounds** in the skin. Fluid from dying cells then coagulates to form the telltale gray or grayish-green membrane. Inside the membrane, the bacteria produce an exotoxin, which is a poisonous secretion that causes the life-threatening symptoms of diphtheria. The exotoxin is carried throughout the body in the bloodstream, destroying healthy tissue in other parts of the body.

The most serious complications caused by the exotoxin are inflammations of the heart muscle (**myocarditis**) and damage to the nervous system. The risk of serious complications is increased as the time between onset of symptoms and the administration of antitoxin increases and as the size of the membrane formed increases. Myocarditis may cause disturbances in the heart rhythm (**arrhythmias**) and may result in **heart failure**. Symptoms of nervous system involvement can include seeing double vision (diplopia), painful or difficult swallowing (dysphagia), and slurred speech or loss of voice, which are all indications of the exotoxin's effect on nerve functions. The exotoxin may also cause severe swelling in the neck ("bull neck").

The signs and symptoms of diphtheria vary according to the location of the infection.

WWW.BOOKBAZ.IR

Nasal

Nasal diphtheria produces few symptoms other than a watery or bloody discharge. On examination, there may be a small visible membrane in the nasal passages. Nasal infection rarely causes complications by itself, but it is a **public health** problem because it spreads the disease more rapidly than other forms of diphtheria.

Pharyngeal

Pharyngeal diphtheria gets its name from the pharynx, which is the part of the upper throat that connects the mouth and nasal passages with the voice box (larynx). This is the most common form of diphtheria, causing the characteristic grayish throat membrane. The membrane often bleeds if it is scraped or cut. It is important not to try to remove the membrane because the **trauma** may increase the body's absorption of the exotoxin. Other signs and symptoms of pharyngeal diphtheria include mild **sore throat**, **fever** of 101–102°F (38.3–38.9°C), a rapid pulse, and general body weakness.

Laryngeal

Laryngeal diphtheria, which involves the voice box or larynx, is the form most likely to produce serious complications. The fever is usually higher in this form of diphtheria (103–104°F or 39.4–40°C) and the patient is very weak. Patients may have a severe **cough**, have difficulty breathing, or lose their voice completely. The development of a "bull neck" indicates a high level of exotoxin in the bloodstream. Obstruction of the airway may result in difficulty breathing, respiratory compromise, and death.

Skin

This form of diphtheria, which is sometimes called cutaneous diphtheria, accounts for about 33% of diphtheria cases. It is found chiefly among people with poor hygiene, and is more common in tropical climates. Any break in the skin can become infected with diphtheria. The infected tissue develops an ulcerated area and a diphtheria membrane may form over the wound but is not always present. The wound or ulcer is slow to heal and may be numb or insensitive when touched.

Diagnosis

Because diphtheria must be treated as quickly as possible, doctors usually make the diagnosis on the basis of the visible symptoms without waiting for test results.

KEY TERMS

Antitoxin—An antibody against an exotoxin, usually derived from horse serum.

Bacillus—A rod–shaped bacterium, such as the diphtheria bacterium.

Carrier—A person who may harbor an organism without symptoms and may transmit it to others.

Cutaneous—Located in the skin.

Diphtheria–tetanus–pertussis (DTP)—The standard preparation used to immunize children against diphtheria, tetanus, and whooping cough. A so-called "acellular pertussis" vaccine (aP) is usually used since its release in the mid-1990s in a combined vaccine known as DTaP.

Exotoxin—A poisonous secretion produced by bacilli that is carried in the bloodstream to other parts of the body.

Gram's stain—A dye staining technique used in laboratory tests to determine the presence and type of bacteria.

Loeffler's medium—A special substance used to grow diphtheria bacilli to confirm a diagnosis.

Myocarditis—Inflammation of the heart tissue.

Toxoid—A preparation made from inactivated exotoxin, used in immunization.

Examination

In making the diagnosis, the doctor examines the patient's eyes, ears, nose, and throat in order to rule out other diseases that may cause fever and sore throat, such as **infectious mononucleosis**, a sinus infection, or **strep throat**. The most important single symptom that suggests diphtheria is the membrane. When a patient develops skin infections during an outbreak of diphtheria, the doctor will consider the possibility of cutaneous diphtheria and take a smear to confirm the diagnosis.

Tests

The diagnosis of diphtheria can be confirmed by the results of a culture obtained from the infected area. Material from the swab is put on a microscope slide and stained using a procedure called Gram's stain. The diphtheria bacillus is called Gram-positive because it holds the dye after the slide is rinsed with alcohol. Under the microscope, diphtheria bacilli look like beaded rod-shaped cells, grouped in patterns that

resemble Chinese characters. Another laboratory test involves growing the diphtheria bacillus on a special material called Loeffler's medium.

Treatment

Diphtheria is a serious disease requiring hospital treatment in an intensive care unit if the patient has developed respiratory symptoms. Treatment includes a combination of medications and supportive care.

Antitoxin

The most important step is prompt administration of diphtheria antitoxin, without waiting for laboratory results. The antitoxin is made from horse serum and works by neutralizing any circulating exotoxin. The doctor must first test the patient for sensitivity to animal serum. Patients who are sensitive (about 10%) must be desensitized with diluted antitoxin, since the antitoxin is the only specific substance that will counteract diphtheria exotoxin. No other type if antitoxin is available for the treatment of diphtheria.

The dose of antitoxin ranges from 20,000–100,000 units, depending on the severity and length of time of symptoms occurring before treatment. Diphtheria antitoxin is usually given intravenously. It must be obtained from the U.S. Centers for Disease Control and Prevention (CDC) and may not be available in some parts of the world.

Antibiotics

Antibiotics are given to kill the bacteria, to prevent the spread of the disease, and to protect the patient from developing **pneumonia**. They are not a substitute for treatment with antitoxin. Both adults and children may be given penicillin, ampicillin, or erythromycin. Erythromycin appears to be more effective than penicillin in treating people who are carriers because of better penetration into the infected area.

Cutaneous diphtheria is usually treated by cleansing the wound thoroughly with soap and water, and giving the patient antibiotics for 10 days.

Supportive care

Diphtheria patients need bed rest with intensive nursing care, including extra fluids, oxygenation, and monitoring for possible heart problems, airway blockage, or involvement of the nervous system. Patients with laryngeal diphtheria are kept in a **croup** tent or high-humidity environment; they may also need throat suctioning or emergency surgery if their airway is blocked.

Patients recovering from diphtheria should rest at home for a minimum of two to three weeks, especially if they have heart complications. In addition, patients should be immunized against diphtheria after recovery, because having the disease does not always induce antitoxin formation and protect them from re-infection.

Prevention of complications

Diphtheria patients who develop myocarditis may be treated with oxygen and with medications to prevent irregular heart rhythms. An artificial pacemaker may be needed. Patients with difficulty swallowing can be fed through a tube inserted into the stomach through the nose. Patients who cannot breathe are usually put on mechanical respirators.

Prognosis

The prognosis depends on the size and location of the membrane and on early treatment with antitoxin; the longer the delay, the higher the death rate. The most vulnerable patients are children under age five and those who develop pneumonia or myocarditis. Death rates generally range from 5–10% and may reach as high as 20% in young children and older adults. Nasal and cutaneous diphtheria are rarely fatal.

Prevention

Prevention of diphtheria has four aspects.

Immunization

Universal immunization is the most effective means of preventing diphtheria. The standard course of immunization for healthy children is three doses of DTaP (diphtheria-tetanus-acellular pertussis) preparation given between two months and six months of age, with booster doses given at 18 months and again between the ages of four and six years. At 12 years a booster shot of is given. Adults should be immunized at 10-year intervals with Td (tetanus-diphtheria) toxoid. A toxoid is a bacterial toxin that is treated to make it harmless but still can induce immunity to the disease.

Isolation of patients

Diphtheria patients must be isolated for one to seven days or until two successive cultures show that they are no longer contagious (up to six weeks). Children placed in **isolation** are usually assigned a primary nurse for emotional support.

WWW.BOOKBAZ.IR

Identification and treatment of contacts

Because diphtheria is highly contagious and has a short incubation period, family members and other contacts of diphtheria patients must be watched for symptoms and tested to see if they are carriers. They are usually given antibiotics for seven days and a booster shot of diphtheria/tetanus toxoid.

Reporting cases to public health authorities

Reporting is necessary to track potential epidemics, to help doctors identify the specific strain of diphtheria, and to see if resistance to penicillin or erythromycin has developed.

Discharge from the hospital

Definition

Discharge from the hospital refers to the point at which a patient leaves the hospital and either returns home or is transferred to another facility such as a **rehabilitation** center or to a nursing home. Part of the discharge process includes giving the patients instructions on how to continue their recovery at home. Discharge planning is a service that considers the patients' needs after a hospital stay and may involve several different services such as visiting nursing care, **physical therapy**, and home blood drawing.

Description

Hospitalization is often a short-term event, so planning for discharge may begin shortly after admission. The physicians, nurses, and case managers involved in a patient's care are part of an assessment team that keeps in mind the patient's preadmission level of independence and decides whether the patient will be able to return home following the hospital stay.

The term "discharge planning" may also be used to refer to helping patients arrange for services such as rehabilitation, physical therapy, **occupational therapy**, visiting nurses, or nursing **home care**. This may be provided by a case manager or by the hospital's social service department. The patient may request assistance or the physician may make the request in the form of a referral to the department. The patient will need to be evaluated to see what services he or she requires, as well as what services he or she qualifies for or what services the patient's insurance will cover. The patient may be discharged with a visit from a visiting nurse taking place later that same day to assess the patient's needs and to make arrangements. If a patient has specific requirements, he or she may be discharged home only after certain equipment, such as a hospital-style bed and oxygen, has been delivered to the home. If a patient feels he or she is being discharged before he or she is ready, the patient can file a complaint with the hospital's ombudsman.

Preparation

When making the decision to discharge a patient, information that could affect the discharge plan should be noted in the patient's medical record. The primary questions include:

- Can this patient return to his or her preadmission living situation?

- Has there been a change in the patient's ability to care for him- or herself?
- Is the patient in need of services to be able to care for him- or herself?
- Which services will the patient need?
- Are there mental health needs that must be met?
- Does the patient agree with the discharge plan?

While a person has been in the hospital, individuals other than the patient's primary care physician may have been in charge of the patient's care. Good discharge planning involves clear communication between the hospital physician(s) and the primary care physician. The information to be conveyed includes:

- a summary of the hospital stay
- a list of test and surgeries performed, with results
- a list of test results still pending
- a list of follow-up tests needed after discharge, if any
- a list of medications the patient is being discharged with, including the dosage and frequency
- a copy of the patient's discharge instructions
- a date when the patient should see the primary-care physician for a follow-up appointment
- the plan for outpatient treatment, if needed, to ensure that responsibility for this treatment has been clearly transferred and that the primary care physician accepts the treatment responsibility
- discharge instructions to the patient on activity level, diet, and wound care

Before leaving the hospital, the patient will receive discharge instructions that should include:

- an explanation of the care received in the hospital
- a list of medications including dosage, times, and frequency
- a list of potential side effects of any newly prescribed medications
- a prescription for any newly prescribed medications
- when to see the primary-care physician for a follow-up appointment
- home-care instructions, such as recommended activity level, diet, restrictions on bathing, and wound care, as well as when the patient can return to work or school or resume driving
- signs of infection or worsening condition, such as pain, fever, bleeding, difficulty breathing, or vomiting
- an explanation of any additional services the patient will be receiving, such as visiting nurse care, including contact information

KEY TERMS

Ombudsman—A patient representative who investigates patient complaints and problems related to hospital service or treatment. He or she may act as a mediator between the patient, the family, and the hospital.

Aftercare

A follow-up visit with either the patient's hospital physician, nurse, or case manager should take place within two weeks after discharge to review the results of any tests that were done in the hospital, to remind the patient to make a follow-up appointment with the physician, to see if the patient has any questions about any new medications that were added in the hospital, and to be sure that no problems arose after discharge that have not been addressed. Such follow-up calls help to ensure a successful recovery.

Complications

Patients may experience a complication or an adverse event, such as an injury or infection, as a result of care received in the hospital. According to a 2013 health article from Wolters Kluwer Health Clinical Solutions, preventing avoidable rehospitalizations has the potential to profoundly improve both the quality of life for patients and the financial well-being of healthcare systems. Complications that result in patient readmissions within 30 days of being discharged are highly scrutinized due to the increase of patient care and costs for insurance, government programs, and medical facilities. In 2012, the U.S. government started to penalize hospitals for excess readmissions, initially involving up to 1% of total payments from Medicare. Approximately two-thirds of these hospitals realized some penalty under this program in 2012.

Discoid lupus erythematosus

Definition

Discoid lupus erythematosus (DLE) is a disease in which coin-shaped (discoid) red bumps appear on the skin.

Discoloration of the hands is one characteristic of discoid lupus erythematosus. *(Custom Medical Stock Photo, Inc.)*

Description

The disease called discoid lupus erythematosus only affects the skin, although similar discoid **skin lesions** can occur in the serious disease called **systemic lupus erythematosus** (SLE). Only about 10% of all patients with DLE will go on to develop the multi-organ disease SLE.

The tendency to develop DLE seems to run in families. Although men or women of any age can develop DLE, it occurs in women three times more frequently than in men. The typical DLE patient is a woman in her 30s.

Causes and symptoms

The cause of DLE is unknown. It is thought that DLE (like SLE) may be an autoimmune disorder. **Autoimmune disorders** are those that occur when cells of the immune system are misdirected against the body. Normally, immune cells work to recognize and help destroy foreign invaders like bacteria, viruses, and fungi. In autoimmune disorders, these cells mistakenly recognize various tissues of the body as foreign invaders, and attack and destroy these tissues. In SLE, the misdirected immune cells are antibodies. In DLE, the damaging cells are believed to be a type of white blood cell called a T lymphocyte. The injury to the skin results in inflammation and the characteristic discoid lesions.

In DLE, the characteristic skin lesion is circular and raised. The reddish rash is about 5–10 mm in diameter, with the center often somewhat scaly and

KEY TERMS

Antibody—Specialized cells of the immune system that can recognize organisms invading the body (like bacteria, viruses, and fungi). The antibodies are then able to start a complex chain of events designed to kill these foreign invaders.

Autoimmune disorder—A disorder in which the body's antibodies mistake the body's own tissues for foreign invaders. The immune system then attacks and causes damage to these tissues.

Immune system—The system of specialized organs, lymph nodes, and blood cells throughout the body that work together to defend the body against foreign invaders (bacteria, viruses, fungi, etc.).

lighter in color than the darker outer ring. The surface of these lesions is sometimes described as "warty." There is rarely any **itching** or **pain** associated with discoid lesions. They tend to appear on the face, ears, neck, scalp, chest, back, and arms. As DLE lesions heal, they leave thickened, scarred areas of skin. When the scalp is severely affected, there may be associated hair loss (**alopecia**).

People with DLE tend to be quite sensitive to the sun. They are more likely to get a **sunburn**, and the sun is likely to worsen their discoid lesions.

Diagnosis

Diagnosis of DLE usually requires a **skin biopsy**. A small sample of a discoid lesion is removed, specially prepared, and examined under a microscope. Usually, the lesion has certain microscopic characteristics that allow it to be identified as a DLE lesion. Blood tests will not reveal the type of antibodies present in SLE, and **physical examination** usually does not reveal anything other than the skin lesions. If antibodies exist in the blood, or if other symptoms or physical signs are found, it is possible that the discoid lesions are a sign of SLE rather than DLE.

Treatment

Treatment of DLE primarily involves the use of a variety of skin creams. **Sunscreens** are used for protection. Steroid creams can be applied to decrease inflammation. Occasionally, small amounts of a steroid preparation will be injected with a needle into a specific lesion. Because of their long list of side effects, steroid preparations taken by mouth are avoided. Sometimes, short-term treatment with oral **steroids** will be used for particularly severe DLE outbreaks. Medications used to treat the infectious diseasemalaria are often used to treat DLE.

Alternatives

Alternative treatments for DLE include eating a healthy diet, low in red meat and dairy products and high in fish containing **omega-3 fatty acids**. These types of fish include mackerel, sardines, and salmon. Following a healthy diet is thought to decrease inflammation. Dietary supplements believed to be helpful include **vitamins** B, C, E, and selenium. **Vitamin A** is also recommended to improve DLE lesions. Constitutional homeopathic treatment can help heal DLE as well as help prevent it from developing into SLE.

Prognosis

For the most part, the prognosis for people with DLE is excellent. While the lesions may be cosmetically unsightly, they are not life threatening and usually do not cause a patient to change his or her lifestyle. Only about 10% of patients with DLE will go on to develop SLE.

Prevention

DLE cannot be prevented. Recommendations to prevent flares of DLE in patients with the disease include avoiding exposure to sun and consistently using sunscreen.

Disk removal

Definition

Disk removal or diskectomy (discectomy) is the surgical removal of part or all of an intervertebral disk—the flexible cushion that separates any two adjacent vertebrae in the spine. Disk removal is performed to relieve intractable back **pain**. If an entire disk is removed, it may be replaced with an artificial disk. If several damaged disks are removed, the vertebrae may be joined together by **spinal fusion**.

Purpose

The bony vertebrae and intervertebral disks of the spine enclose and protect the spinal cord. Nerve roots branch out from both sides of the spinal cord through passages in the vertebrae called foramina that are formed by the bony laminae of the vertebrae. The intervertebral disks act as **shock** absorbers, protecting the brain and spinal cord from the impact produced by bodily movements. As people age, however, the disks between vertebrae, especially those in the lower (lumbar) spine and the cervical spine (the neck) can begin to dry out, weaken, and degenerate. Tears may form in the fibers that hold a disk in place (so that the disk slips out of position), the soft gel inside a disk can bulge out through the disk wall, or the disk may rupture. These conditions are referred to as herniated, prolapsed, slipped, or ruptured disks. Such disks can put pressure on, pinch, or compress the spinal cord or the nerve roots, causing back or neck pain. Symptoms of a **herniated disk** often improve or disappear with anti-inflammatory medications, **physical therapy**, and/or **exercise**. If not, disk removal may be necessary. Because the goal of disk removal is to relieve the pressure on nerve roots, the procedure is sometimes referred to as decompression.

One or more damaged disks in the lumbar spine that cause severe back pain or numbness or muscle weakness in a leg or buttock may require a lumbar diskectomy. Damaged lumbar disks can also result in bladder or bowel dysfunction, which may require immediate disk removal.

Cervical disk problems can compress the spinal nerves in the neck, with symptoms ranging from mild neck pain to numbness in a hand; shooting pains in the shoulder, arm, and hand; and possibly weakness in the arm and hand. Although cervical spine disease can usually be treated without surgery, sometimes it becomes so severe that a diskectomy is required to relieve the pain.

Demographics

Low back pain is a major cause of disability in the United States and around the world. An estimated 70–80% of people experience low back pain at some point in their lives. Cervical spine disease is also a fairly common problem in adults. As a result, disk removal is one of the most common types of back surgery, with at least 200,000 diskectomies performed in the United States each year.

Description

Traditional disk removal is an open diskectomy in the lumbar or cervical spine performed under general **anesthesia**. However, disk removal can often be accomplished with a minimally invasive microdiskectomy. Disk removal surgery is often combined with spinal fusion or other procedures.

Disk removal is performed by an orthopedic surgeon or neurosurgeon in a hospital setting. Microdiskectomy may be performed in an outpatient surgical facility. Spine surgeons may perform anterior disk surgeries in conjunction with a vascular surgeon who moves aside the large blood vessels that lie on top of the spine and continue down the legs.

Open diskectomies

For a lumbar diskectomy, an incision of 5–6 in. (13–15 cm) is made in the back over the injured disk. The muscles, dura mater (the membrane surrounding the spinal cord and nerve roots), and the bundle of nerves known as the "cauda equina" (horse's tail) are moved aside to expose the spine and damaged disk. A small part of the lamina bone of the vertebra is cut away to provide an opening. A small hole is cut in the damaged disk, and the material inside the disk is removed. Depending on the damage and position of the disk, other portions of the disk or the entire disk are removed. Screws, cages, and any bone graft materials are set in place to stabilize the spine and promote healing. A lumbar diskectomy may be performed in conjunction with a **laminectomy** to remove the lamina or foraminotomy to take pressure off a nerve.

Posterior cervical foraminotomy for a pinched spinal nerve is performed through a 1–2 in. (2.5–5 cm) incision in the back of the neck. Under magnification, the soft tissue is dissected away. The outer wall of the foramen is removed, the nerve root is gently lifted, the disk material is removed, and the wound is closed. This procedure creates more space for the nerve to pass through without requiring spinal fusion.

KEY TERMS

Anterior cervical diskectomy and fusion (ACDF)—Disc removal and spinal fusion performed through the front of the neck.

Anterior lumbar interbody fusion (ALIF)—Spinal fusion performed through the left side of the abdomen following disk removal.

Cauda equina—A bundle of nerve roots in the lower (lumbar) region of the spinal canal that controls the leg muscles and functioning of the bladder, intestines, and genitals.

Computed tomography (CT) scan—An imaging technique that produces three-dimensional pictures of organs and structures inside the body using a 360° x-ray beam.

Decompression—Surgery such as disk removal that relieves pressure on the nerve roots of the spine.

Diskectomy—Discectomy; the surgical removal of a portion or all of an intervertebral disk.

Dura mater—The outermost and strongest of the three membranes that cover the brain and spinal cord including the nerves of the cauda equina.

Fluoroscopy—A technique for observing inside the body through shadows cast on a fluorescent screen by x-rays passing through internal structures.

Foramen (plural, foramina)—The opening in a vertebra through which the nerves branch out from the spinal cord.

Foraminotomy—Surgery to take pressure off nerves in a foramen; often combined with disk removal.

Herniated disk—A blister-like bulging or protrusion of the contents of an intervertebral disk; also called a prolapsed, slipped, displaced, or ruptured disk.

Intervertebral disk—The cylindrical elastic-like gel pad that connects and separates each pair of vertebrae in the spine.

Lamina—The neural arch of a vertebra.

Laminectomy—Surgical removal of the lamina to reach and remove a herniated disk.

Magnetic resonance imaging (MRI)—A procedure that visualizes organs and structures inside the body using a magnetic field and pulses of energy.

Microdiskectomy—Microdecompression; minimally invasive spinal surgery (MISS) for disk removal.

Myelogram—Images of the spine produced with x-rays or CT scans and a special dye.

Spinal fusion—Fusion of two or more vertebrae following disk removal.

Vertebrae—The bones of the spine or backbone that enclose the spinal cord.

Microdiskectomy

When very little additional surgery is required on the bones, joints, ligaments, or muscles of the spine, disk removal is accomplished with a minimally invasive spine surgery (MISS) called microdiskectomy or microdecompression. Microdiskectomy is performed either under spinal anesthesia, with the patient awake, or under general anesthesia. An incision of 1–1.5 in. (2.5–3.8 cm) or less is made in the back or neck over the position of the herniated disk, and the muscles are moved away from the spine. A tool called a tubular retractor is inserted through the skin and soft tissues, creating a tunnel to the spinal column. The retractor holds the muscles open during the procedure, and tiny instruments are fitted through its center. Using a special microscope to magnify the view through the retractor, the surgeon locates the nerve root and moves it away. A small amount of the lamina bone is removed to reveal the spinal nerve and disk. The damaged disk tissue and pieces are removed through the retractor. The disk is replaced with bone graft material, and any other materials (such as screws or rods needed for spinal fusion) are inserted through the retractor. The retractor is removed, the muscles are replaced, and the incision is closed with stitches or staples. Fluoroscopy is used to display real-time x-ray images on a screen throughout the procedure. The procedure takes 1–2 hours.

MISS techniques have been used for decompression and spinal fusion since the 1990s. Video-assisted microdiskectomy minimizes damage to nearby muscles, spinal structures, and other tissues. The incision is smaller than with open surgery, and there is less bleeding. Microdiskectomy reduces the length of the hospital stay, the use of postoperative pain-relieving **narcotics**, and the recovery period.

Disk replacements and spinal fusions

A worn or degenerated lumbar disk may be replaced with a mechanical disk that can restore

WWW.BOOKBAZ.IR

motion to the spine. Previously available only in Europe, artificial disk replacement was first approved by the U.S. Food and Drug Administration (FDA) in 2004. Numerous disk designs have since been developed and tested.

The removal of disks between two or more vertebrae can make the spine unstable, so disk removal may be accompanied by spinal fusion, in which the bones of the vertebrae are roughened so that they grow together. Bone strips taken from the patient's leg or hip may be used to help hold the vertebrae together. Spinal fusion decreases pain, but also decreases spinal mobility. Posterior lumbar interbody fusion (PLIF) is a common technique for fusing lumbar vertebrae through the back following disk removal.

Anterior lumbar interbody fusion (ALIF) surgery was first performed in the 1950s, but had a high failure rate. It was reintroduced in the 1990s with the development of threaded titanium cages that better supported the emptied disk space and resulted in a higher fusion rate. ALIF is performed through a 3–5 in. (8–13 cm) incision on the left side of the abdomen, with the abdominal muscles retracted. ALIF is now often combined with an approach from the back called anterior/posterior fusion. This procedure results in greater stability after the collapse of a large amount of disk space, as can occur with conditions such as degenerative disk disease.

Anterior cervical diskectomy and fusion (ACDF) is performed through the front of the neck. The disk material is removed, and bone graft material and metal hardware are inserted for stabilization.

Preparation

A clinical exam, x-ray, and neuroimaging studies, including a computed tomography (CT) scan, myelogram, and **magnetic resonance imaging** (MRI), are used to determine the precise location and condition of the affected disk. Prior to surgery, patients should prepare their homes for their recovery. Smokers should stop, since **smoking** can slow recovery. Patients may need to stop taking drugs such as **aspirin**, ibuprofen, naproxen, and others that can interfere with blood clotting, as well as **vitamins**, herbs, or supplements. Patients with underlying medical conditions should visit their regular doctor prior to surgery. Patients may also want to visit a physical therapist to learn exercises to perform before surgery and to practice using crutches.

Patients are usually asked not to eat or drink for 6–12 hours before surgery. Any necessary medications should be taken with a small sip of water. Patients should bring their cane, walker, or wheelchair to the hospital, if they require one, as well as shoes with flat, nonskid soles. Patients may be given an injection to induce drowsiness an hour before surgery, or they may be given prophylactic **antibiotics** right before they are taken to the operating room.

Aftercare

After posterior surgery, the patient may need to rest lying down. Other patients will be asked to get up and walk around as soon as the anesthesia wears off. Microdiskectomy patients leave the hospital within two or three days or may even be driven home on the same day as the surgery. Open diskectomy patients may need to stay in the hospital for four or five days. There may be pain or stiffness in the back or neck. Microdiskectomy patients usually experience less postoperative pain, because minimally invasive procedures do not disrupt muscles or soft tissues. Discomfort can be managed or relieved with medications. After cervical disk removal, patients may be given a soft collar to wear around the neck.

Most diskectomy patients can resume normal activities in four to six weeks. Until then, they must:

- avoid sitting for more than 15–20 minutes
- use a reclined chair
- avoid bending at the waist, twisting, or lifting heavy objects
- begin gentle walking, with a gradual increase in exercise over about four weeks
- begin stationary biking or gentle swimming after two weeks
- sleep on a firm mattress
- slow down if they experience more than minor pain in the back or legs

Depending on the procedure and the patient's general condition, physical therapy may be recommended. If disk removal included a fusion procedure, pain usually resolves quickly, but it may take several months before the bone is solid. During healing, the fused spine must be kept in proper alignment, and patients are taught how to move, reposition, sit, stand, and walk properly.

Risks

All surgery carries small risks for heart and lung problems, bleeding, or reactions to the anesthesia. The

most common risk of disk removal surgery is infection, which occurs in 1–2% of cases. Occasionally, there may be some residual **paralysis** of a leg or bladder muscle as a result of the disk problem that necessitated the surgery. Open surgery requires retracting muscle, which can damage the muscle or surrounding soft tissue, cause postsurgical pain, and require a longer recovery period. Additional risks from diskectomy include:

- damage to nerves coming out of the spine, which may cause permanent pain or weakness
- damage to major blood vessels in front of the disk
- back pain that does not improve or that returns after surgery
- pain due to failure to remove all of the disk fragments
- leakage of spinal fluid
- repeated slippage of the disk

There are few risks to posterior cervical foraminotomy. However, in addition to bleeding or infection, risks may include neck stiffness, repeat disk herniation, damage to the nerve root or spinal cord, or incomplete relief of symptoms.

Results

In properly evaluated patients, there is a very good chance that disk removal will ease pain and improve movement. The surgery relieves neck, back, or leg pain in up to 90% of patients, including those over age 60. **Numbness and tingling** usually improve or disappear. Failure to achieve pain relief can be due to a variety factors, including the length of time patients lived with the disk condition before surgery and the presence of nerve damage or other spinal conditions.

Alternatives

Disk removal surgery is usually a last resort for patients whose back or neck pain does not improve with medical treatment or physical therapy. However, bladder or bowel dysfunction due to a damaged disk requires emergency disk removal.

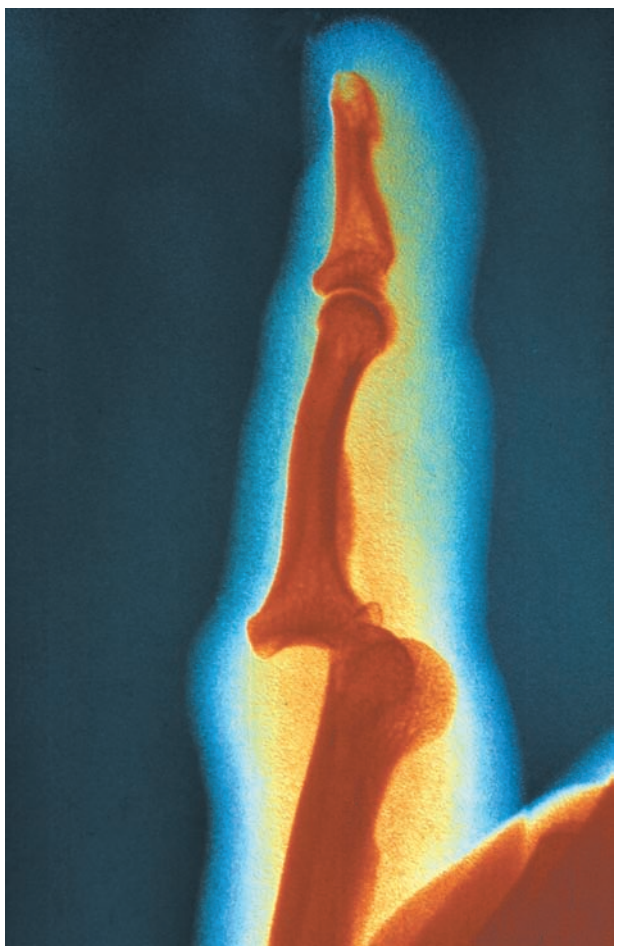
Dislocations and subluxations

Definition

In medicine, the terms dislocation and subluxation refer to the displacement of bones that form a joint. These conditions affecting the joint most often result from **trauma** that causes adjoining bones to no longer align with each other. A partial or incomplete dislocation is called a subluxation.

Description

In a healthy joint, the bones are normally held together with tough, fibrous bands called ligaments. These ligaments are attached to each bone along with a fibrous sac surrounding the joint called the articular capsule or joint capsule. The ligaments and joint capsule are relatively strong and nonelastic but permit movement within normal limits for each particular joint. In the event of a dislocation, one of the bones making up the joint is forced out of its natural alignment from excessive stretching and tearing of the joint ligaments and capsule. Muscles and tendons surrounding the joint are usually stretched and injured to some degree.



This x ray shows the dislocation between two bones in a finger. *(Photo Researchers, Inc.)*

Causes and symptoms

A violent movement at the joint that exceeds normal limits usually causes a joint dislocation. Although dislocations often result from trauma, they sometimes occur as a result of disease affecting the joint structures. In the process of the dislocation, there is tearing of the ligaments and the articular capsule, which are vital structures for connecting the bone. Following a dislocation, the bones affected are often immobile and the affected limb may be locked in an abnormal position; **fractures** are also a concern with severe dislocations.

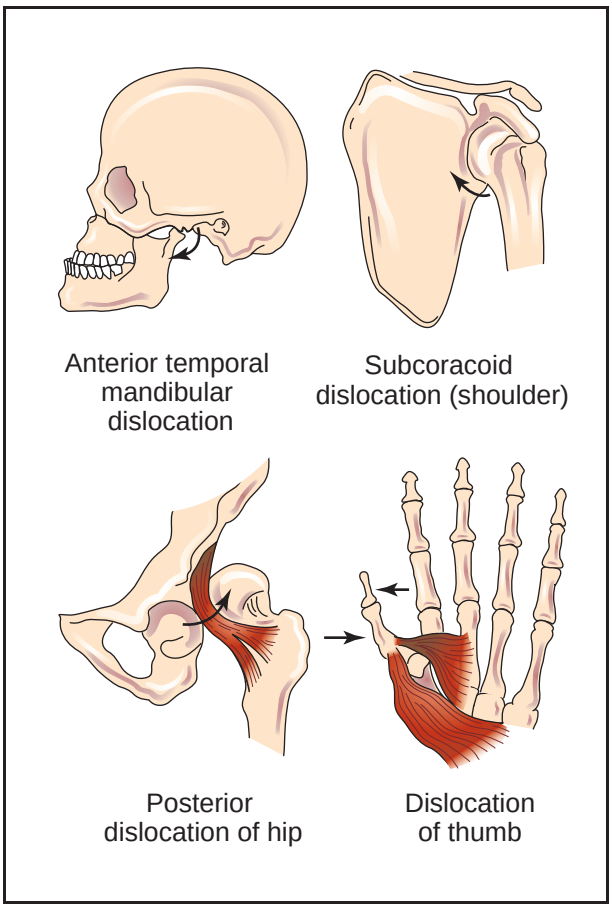
Important factors in recognizing a dislocation or subluxation include a history of experiencing a fall or receiving a blow in a particular joint followed by the sudden onset of loss of function to the involved limb. Immediately after the dislocation, the joint almost always swells significantly and feels painful when pressure is applied (point tenderness). If trauma to the joint causing the dislocation or subluxation is violent in nature, small chips of bone can be torn away with the supporting structures. Chronic recurrent dislocations may take place without severe **pain** because of the somewhat slack condition of the surrounding muscles and other supporting tissues. A first-time dislocation is considered and treated as a possible fracture. Risk factors that can increase susceptibility of joint dislocation and subluxation are shallow or abnormally formed joint surfaces present at birth (congenital) and/or other diseases of ligaments and tissue around a joint. Some infants are born with a hip dislocation. Both sexes and all ages are affected.

Diagnosis

A thorough medical history and physical exam by a physician is the first step in the correct diagnosis of dislocations and subluxations. X rays of the joint and adjacent bones can locate and help determine the extent of dislocated joints.

Treatment

Immediately after the dislocation, the application of ice is helpful to control swelling and decrease pain. If the patient needs to be transported, it is important to prevent the joint from moving (**immobilization**). At



Dislocations and subluxations refer to the displacement of bones that form a joint. Such conditions most often result from trauma causing adjoining bones to no longer touch each other. A partial or incomplete dislocation is called a subluxation. *(Illustration by Electronic Illustrators Group. © Cengage Learning®.)*

times, a cast or splint may be used to immobilize the joint and ensure proper alignment and healing. The treatment of realigning bones following a dislocation is called reduction. This may include simple maneuvers that manipulate the joint to reposition the bones or surgical procedures to restore the joint to its normal position. A general **anesthesia** or muscle relaxant may be used to help make joint reduction possible by relaxing surrounding muscles in spasm. **Acetaminophen** or **aspirin** are sometimes used to control moderate pain, and **narcotics** may be prescribed by the physician if the pain is severe. Recurring dislocation may require surgical reconstruction or replacement of the joint. It is not recommended to attempt to reset a dislocated joint outside of a medical environment with experienced medical personnel, because a fracture may be present.

KEY TERMS

Articular capsule—An envelope of tissue that surrounds a free moving joint, composed of an external layer of white fibrous tissue and an external synovial membrane that secretes a lubricant into the joint.

Alternatives

Chiropractic care has been shown to be effective for joint subluxation and dislocation, especially in the spine. Swelling can be addressed using botanical therapies. Bromelain, a pineapple enzyme, and turmeric (*Curcuma longa*) are the most potent botanical remedies for this purpose. Acute homeopathic care with *arnica* (*Arnica montana*) can reduce the trauma to the body. Ligament and tendon strengthening can be assisted both botanically and homeopathically.

Prognosis

Joint ligaments have poor blood supply and, therefore, heal slowly. This healing process continues long after the symptoms of the dislocation injury have diminished. Once a joint has been either subluxated or completely dislocated, the connective tissue binding or holding it in correct alignment is stretched to such an extent that the joint becomes extremely vulnerable to repeated dislocations. However, this chance of recurrent dislocation and subluxation will decrease if a proper **rehabilitation** program is implemented to strengthen surrounding muscles of the joint. Most joint dislocations are curable with prompt treatment. After the dislocation has been corrected, the joint may require immobilization with a cast or sling for two to eight weeks.

Prevention

When an individual is involved in strenuous sports or heavy work, involved joints may be protected by elastic bandage wraps, tape wraps, knee and shoulder pads, or special support stockings. Keeping the muscles surrounding the joint strong will also help prevent dislocations. Long-term problems may also be prevented by allowing an adequate amount of time for an injured joint to rest and heal prior to resuming full activity.

Dissociative disorders

Definition

The dissociative disorders are a group of mental disorders that affect consciousness defined as causing significant interference with the patient's general functioning, including social relationships and employment.

Demographics

The dissociative disorders vary in their severity and the suddenness of onset. It is difficult to give statistics for their frequency in the United States because they are a relatively new category and are often misdiagnosed. Criteria for diagnosis require significant impairment in social or vocational functioning.

Description

In order to have a clear picture of these disorders, dissociation should first be understood. Dissociation is a mechanism that allows the mind to separate or compartmentalize certain memories or thoughts from normal consciousness. These split-off mental contents are not erased. They may resurface spontaneously or be triggered by objects or events in the person's environment.

Dissociation is a process that occurs along a spectrum of severity. It does not necessarily mean that a person has a dissociative disorder or other mental illness. A mild degree of dissociation occurs with some physical stressors; people who have gone without sleep for a long period of time, have had "laughing gas" for dental surgery, or have been in a minor accident often have brief dissociative experiences. Another example of dissociation is a person becoming involved in a book or movie so completely that the surroundings or the passage of time are not noticed. Another example might be driving on the highway and taking several exits without noticing or remembering. Dissociation is related to hypnosis in that hypnotic trance also involves a temporarily altered state of consciousness. Most patients with dissociative disorders are highly hypnotizable.

People in other cultures sometimes have dissociative experiences in the course of religious (in certain trance states) or other group activities. These occurrences should not be judged in terms of what is considered "normal" in the United States.

Moderate or severe forms of dissociation are caused by such traumatic experiences as childhood **abuse**, combat, criminal attacks, brainwashing in hostage situations, or involvement in a natural or transportation disaster. Patients with **acute stress disorder**, **post-traumatic stress disorder** (PTSD), or conversion disorder and somatization disorder may develop dissociative symptoms. Recent studies of **trauma** indicate that the human brain stores traumatic memories in a different way than normal memories. Traumatic memories are not processed or integrated into a person's ongoing life in the same fashion as normal memories. Instead, they are dissociated, or split off, and may erupt into consciousness from time to time without warning. The affected person cannot control or "edit" these memories. Over a period of time, these two sets of memories, the normal and the traumatic, may coexist as parallel sets without being combined or blended. In extreme cases, different sets of dissociated memories may alter subpersonalities of patients with dissociative identity disorder (**multiple personality disorder**).

Dissociative amnesia

Dissociative **amnesia** is a disorder in which the distinctive feature is the patient's inability to remember important personal information to a degree that cannot be explained by normal forgetfulness. In many cases, it is a reaction to a traumatic accident or witnessing a violent crime. Patients with dissociative amnesia may develop depersonalization or trance states as part of the disorder, but they do not experience a change in identity.

Dissociative fugue

Dissociative fugue is a disorder in which a person temporarily loses his or her sense of personal identity and travels to another location where he or she may assume a new identity. Again, this condition usually follows a major stressor or trauma. Apart from inability to recall their past or personal information, patients with dissociative fugue do not behave strangely or appear disturbed to others. Cases of dissociative fugue are more common in wartime or in communities disrupted by a natural disaster.

Depersonalization disorder

Depersonalization disorder is a disturbance in which the patient's primary symptom is a sense of detachment from the self. Depersonalization as a symptom (not as a disorder) is quite common in college-age populations. It is often associated with **sleep deprivation** or recreational drug use. It may be accompanied by derealization (where objects in an environment appear altered). Patients sometimes describe depersonalization as feeling like a robot or watching themselves from the outside. Depersonalization disorder may also involve feelings of numbness or loss of emotional "aliveness."

Dissociative identity disorder (DID)

Dissociative identity disorder (DID) is the newer name for multiple personality disorder (MPD). DID is considered the most severe dissociative disorder and involves all of the major dissociative symptoms.

Dissociative disorder not otherwise specified (DDNOS)

DDNOS is a diagnostic category ascribed to patients with dissociative symptoms that do not meet the full criteria for a specific dissociative disorder.

Causes and symptoms

The moderate to severe dissociation that occurs in patients with dissociative disorders is understood to result from a set of causes:

- an innate ability to dissociate easily
- repeated episodes of severe physical or sexual abuse in childhood
- lack of a supportive or comforting person to counteract abusive relative(s)
- the influence of other relatives with dissociative symptoms or disorders

The relationship of dissociative disorders to childhood abuse has led to intense controversy and lawsuits concerning the accuracy of childhood memories. The brain's storage, retrieval, and interpretation of memories are still not fully understood. Controversy also exists regarding how much individuals presenting dissociative disorders have been influenced by books and movies to describe a certain set of symptoms (scripting).

Amnesia

Amnesia in a dissociative disorder is marked by gaps in a patient's memory for long periods of time or for traumatic events. Doctors can distinguish this type of amnesia from loss of memory caused by head injuries or drug intoxication, because the amnesia is "spotty" and related to highly charged events and feelings.

Depersonalization

Depersonalization is a dissociative symptom in which the patient feels that his or her body is unreal, is changing, or is dissolving. Some patients experience depersonalization as being outside their bodies or watching a movie of themselves.

Derealization

Derealization is a dissociative symptom in which the external environment is perceived as unreal. The patient may see walls, buildings, or other objects as changing in shape, size, or color. In some cases, the patient may feel that other persons are machines or robots, though the patient is able to acknowledge the unreality of this feeling.

Identity disturbances

Patients with dissociative fugue, DDNOS, or DID often experience confusion about their identities or even assume new identities. Identity disturbances result from the patient having split off entire personality traits or characteristics as well as memories. When a stressful or traumatic experience triggers the reemergence of these dissociated parts, the patient may act differently, answer to a different name, or appear confused by his or her surroundings.

Diagnosis

Examination

When a doctor is evaluating a patient with dissociative symptoms, he or she will first rule out physical conditions that sometimes produce amnesia, depersonalization, or derealization. These physical conditions include **epilepsy**, head injuries, brain disease,

WWW.BOOKBAZ.IR

side effects of medications, substance abuse, intoxication, **AIDS**, **dementia** complex, or recent periods of extreme physical **stress** and sleeplessness. In some cases, the doctor may give the patient an electroencephalogram (EEG) to exclude epilepsy or other seizure disorders.

Tests

If the patient appears to be physically normal, the doctor will rule out psychotic disturbances, including **schizophrenia**. In addition, doctors can use some **psychological tests** to narrow the diagnosis. One is a screener, the Dissociative Experiences Scale (DES). If the patient has a high score on this test, he or she can be evaluated further with the Dissociative Disorders Interview Schedule (DDIS) or the Structured Clinical Interview for *DSM-5* Dissociative Disorders (SCID-D). It is also possible for doctors to measure a patient's hypnotizability as part of a diagnostic evaluation.

Treatment

Treatment of the dissociative disorders often combines several methods.

Drugs

Some doctors prescribe tranquilizers or antidepressants for the **anxiety** and/or depression that often accompany dissociative disorders. Patients with dissociative disorders are at risk for abusing or becoming dependent on medications.

Alternatives

Patients with dissociative disorders often require treatment by a therapist with some specialized understanding of dissociation. This background is particularly important if the patient's symptoms include identity problems. Many patients with dissociative disorders are helped by both group and individual treatment.

Hypnosis is frequently recommended as a method of treatment for dissociative disorders, partly because hypnosis is related to the process of dissociation. Hypnosis may help patients recover repressed ideas and memories. Therapists treating patients with DID sometimes use hypnosis in the process of "fusing" the patient's alternate personalities.

Prognosis

Prognoses for dissociative disorders vary. Recovery from dissociative fugue is usually rapid.

KEY TERMS

Amnesia—A general medical term for loss of memory that is not due to ordinary forgetfulness. Amnesia can be caused by head injuries, brain disease, or epilepsy, as well as by dissociation.

Depersonalization—A dissociative symptom in which the patient feels that his or her body is unreal, is changing, or is dissolving.

Derealization—A dissociative symptom in which the external environment is perceived as unreal.

Dissociation—A psychological mechanism that allows the mind to split off traumatic memories or disturbing ideas from conscious awareness.

Fugue—A dissociative experience during which a person travels away from home, has amnesia for their past, and may be confused about their identity but otherwise appear normal.

Hypnosis—The means by which a state of extreme relaxation and suggestibility is induced: used to treat amnesia and identity disturbances that occur in dissociative disorders.

Multiple personality disorder (MPD)—An older term for dissociative identity disorder (DID).

Trauma—A disastrous or life-threatening event that can cause severe emotional distress, including dissociative symptoms and disorders.

Dissociative amnesia may resolve quickly, but can become a chronic disorder in some patients. Depersonalization disorder, DDNOS, and DID are usually chronic conditions. DID often requires five or more years of treatment for recovery.

Prevention

Since the primary cause of dissociative disorders is thought to involve extended periods of humanly inflicted trauma, prevention depends on the elimination of **child abuse** and psychological abuse of adult prisoners or hostages.

Dissociative identity disorder *see* **Multiple personality disorder**

Distal pancreatectomy

Definition

A distal **pancreatectomy** is the partial surgical removal of the pancreas, meaning that only the body and tail of the pancreas are removed and the head of the organ is left attached. A total pancreatectomy is the removal of the entire organ, usually along with the spleen, gallbladder, common bile duct, and portions of the small intestine and stomach. When the duodenum is removed along with all or part of the pancreas, the procedure is called a pancreaticoduodenectomy, which surgeons sometimes refer to as "Whipple's procedure." Pancreaticoduodenectomies are increasingly used to treat a variety of malignant and benign diseases of the pancreas. This procedure often involves removal of the regional lymph nodes as well.

Purpose

A distal pancreatectomy is the most effective treatment for a cancerous tumor of the tail or bottom half of the pancreas (islet cell tumors), an abdominal organ that secretes digestive enzymes, insulin, and other hormones. The thickest part of the pancreas near the duodenum (a part of the small intestine) is called the head, the middle part is called the body, and the thinnest part adjacent to the spleen is called the tail.

While surgical removal of tumors in the pancreas is the preferred treatment, it is only possible in the 10–15% of patients who are diagnosed early enough for a potential cure. Patients who are considered suitable for surgery usually have small tumors in the head of the pancreas (close to the duodenum, or first part of the small intestine), have **jaundice** as their initial symptom, and have no evidence of metastatic disease (spread of cancer to other sites). The stage of the cancer will determine whether the pancreatectomy to be performed should be total or distal.

A distal pancreatectomy may be indicated when the pancreas has been severely injured by **trauma**, especially injury to the body and tail of the pancreas. While such surgery removes normal pancreatic tissue as well, the long-term consequences of this surgery are minimal, with virtually no effects on the production of insulin, digestive enzymes, and other hormones.

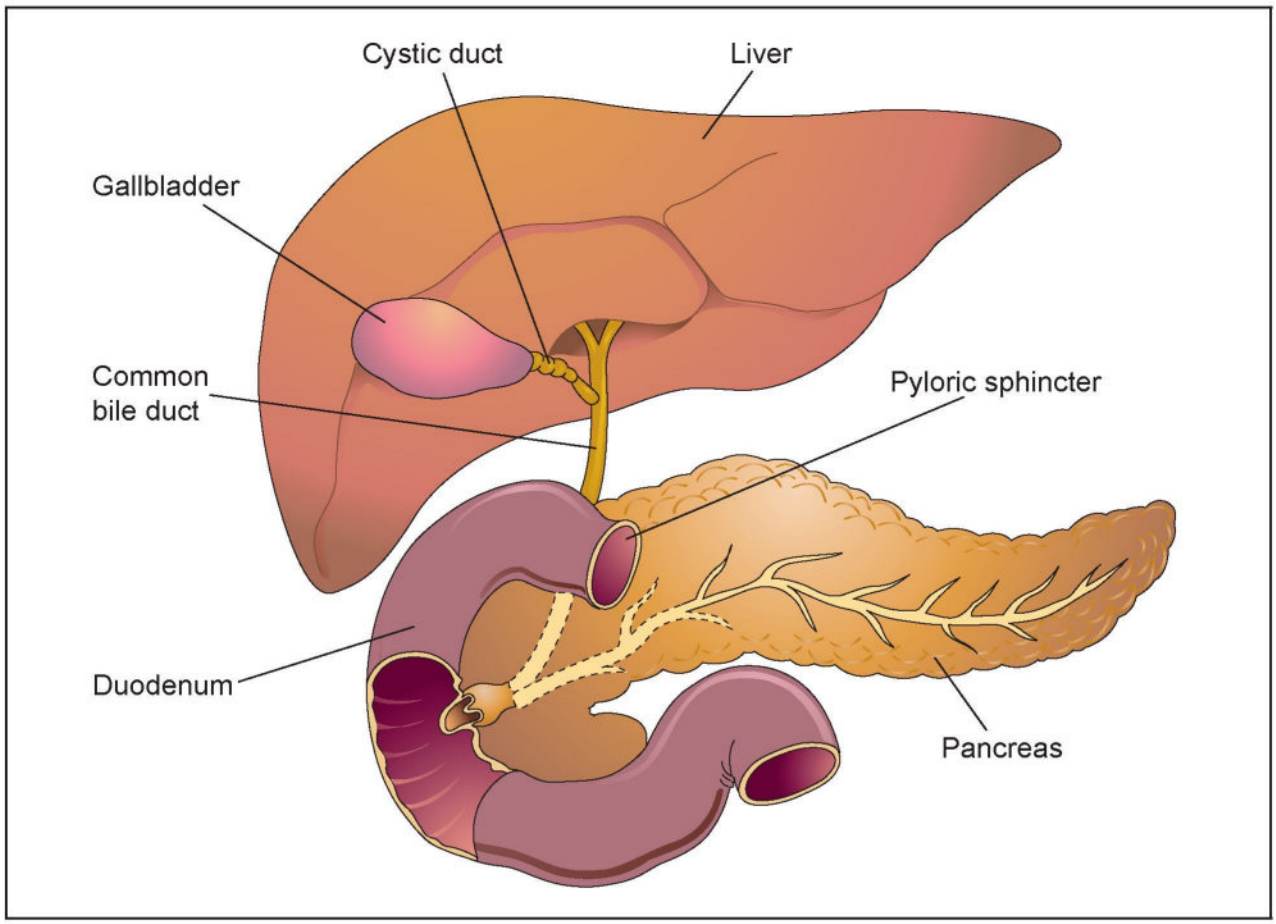
Description

A distal pancreatectomy can be performed through an open surgery technique, in which case one large incision is made, or it can be performed laparoscopically, in which case the surgeon makes four small incisions to insert tube-like surgical instruments. The abdomen is filled with gas, usually carbon dioxide, to help the surgeon view the abdominal cavity. A camera is inserted through one of the tubes and displays images on a monitor in the operating room. Other instruments are placed through the additional tubes. The laparoscopic approach allows the surgeon to work inside the patient's abdomen without making a large incision.

In a distal pancreatectomy, the surgeon clamps and cuts the blood vessels, and the pancreas is stapled and divided for removal. If the disease affects the splenic artery or vein, the spleen is also removed.

During the procedure, several tubes are also inserted for postoperative care. To prevent tissue fluid from accumulating in the operated site, a temporary

WWW.BOOKBAZ.IR



(Illustration by Electronic Illustrators Group. © Cengage Learning®.)

drain leading out of the body is inserted, as well as a **gastrostomy** or g-tube leading out of the stomach in order to help prevent **nausea and vomiting**. A jejunostomy or j-tube may also be inserted into the small intestine as a pathway for supplementary feeding.

Diagnosis/Preparation

Patients with symptoms of a pancreatic disorder undergo a number of tests before surgery is even considered. These can include ultrasonography, x-ray examinations, **computed tomography scans** (CT scan), and **endoscopic retrograde cholangiopancreatography** (ERCP), a specialized imaging technique to visualize the ducts that carry bile from the liver to the gallbladder. Tests may also include **angiography**, another imaging technique used to visualize the arteries feeding the pancreas, and needle aspiration **cytology**, in which cells are drawn from areas suspected to contain cancer. Such tests are required to establish a correct diagnosis for the pancreatic disorder and in the planning the surgery.

Since many patients with pancreatic cancer are undernourished, appropriate nutritional support, sometimes by **tube feedings**, may be required prior to surgery.

Some patients with pancreatic cancer deemed suitable for a distal pancreatectomy will also undergo **chemotherapy** and/or **radiation therapy**. This treatment is aimed at shrinking the tumor, which will improve the chances for successful surgical removal. Sometimes, patients who are not initially considered surgical candidates may respond so well to chemoradiation that surgical treatment becomes possible. Radiation therapy may also be applied during the surgery (intraoperatively) to improve the patient's chances of survival, but this treatment is not yet in routine use. Some studies have shown that intraoperative radiation therapy extends survival by several months.

KEY TERMS

Chemotherapy—A cancer treatment that uses synthetic drugs to destroy the tumor either by inhibiting the growth of the cancerous cells or by killing the cancer cells.

Computed tomography (CT) scan—An imaging technique that creates a series of pictures of areas inside the body, taken from different angles. The pictures are created by a computer linked to an x-ray machine.

Endoscopic retrograde cholangiopancreatography (ERCP)—A procedure to x ray the ducts (tubes) that carry bile from the liver to the gallbladder and from the gallbladder to the small intestine.

Laparoscopy—In this procedure, a laparoscope (a thin, lighted tube) is inserted through an incision in the abdominal wall to determine if the cancer is within the pancreas only or has spread to nearby tissues and if it can be removed by surgery later. Tissue samples may be removed for biopsy.

Magnetic resonance imaging (MRI)—A procedure in which a magnet linked to a computer is used to create detailed pictures of areas inside the body.

Pancreas—A large gland located on the back wall of the abdomen, extending from the duodenum (first part of the small intestine) to the spleen. The pancreas produces enzymes essential for digestion, and the hormones insulin and glucagon, which play a role in diabetes.

Pancreaticoduodenectomy—Removal of all or part of the pancreas along with the duodenum. Also known as "Whipple's procedure" or "Whipple's operation."

Pancreatitis—Inflammation of the pancreas, either acute (sudden and episodic) or chronic, usually caused by excessive alcohol intake or gallbladder disease.

Positron emission tomography (PET) scan—An imaging system that creates a picture showing the location of tumor cells in the body. A substance called radionuclide dye is injected into a vein, and the PET scanner rotates around the body to create the picture. Malignant tumor cells show up brighter in the picture because they are more active and take up more dye than normal cells.

Radiation therapy—A treatment using high energy radiation from x-ray machines, cobalt, radium, or other sources.

Ultrasonogram—A procedure where high-frequency sound waves that cannot be heard by human ears are bounced off internal organs and tissues. These sound waves produce a pattern of echoes which are then used by the computer to create sonograms, or pictures of areas inside the body.

Patients undergoing distal pancreatectomy that involves removal of the spleen may receive preoperative medication to decrease the risk of infection.

Aftercare

Extended hospitalization is usually required for an open distal pancreatectomy, with an average hospital stay of one to two weeks. Recovery time is much quicker with laparoscopic distal pancreatectomy.

Some pancreatic cancer patients may also receive combined chemotherapy and radiation therapy after surgery. This additional treatment has been clearly shown to enhance survival rates.

After surgery, patients experience **pain** in the abdomen and are prescribed pain medication. Follow-up exams are required to monitor the patient's recovery and remove implanted tubes.

In some cases of distal pancreatectomies, pancreatic insufficiency may arise. This is a condition caused because food can no longer be normally processed with the enzymes normally produced by the pancreas. Insulin secretion is likewise no longer possible. These conditions are treated with pancreatic enzyme replacement therapy, which supplies digestive enzymes; and with insulin injections. The occurrence of pancreatic insufficiency after distal pancreatectomy is dependent upon the patient's general health condition before surgery and on the extent of pancreatic tissue removal.

Risks

The most common complication is pancreatic fluid leak at the site of the cut.

Results

Patients usually resume normal activities within a month after surgery, although they are asked to avoid heavy lifting for six to eight weeks and not to drive as long as they take narcotic medication.

When a distal pancreatectomy is performed for chronic **pancreatitis**, the majority of patients obtain

WWW.BOOKBAZ.IR

some relief from pain. Some studies report that one-half to three-quarters of patients become free of pain.

The mortality rate for pancreatectomy has decreased in recent years to 5–10%, depending on the extent of the surgery and the experience of the surgeon. A study of 650 patients at Johns Hopkins Medical Institution, Baltimore, found that only nine patients, or 1.4%, died from complications related to surgery.

Unfortunately, pancreatic cancer is the most lethal form of gastrointestinal malignancy. However, for a highly selective group of patients, a pancreatectomy offers a chance for cure, especially when performed by experienced surgeons. The risk for tumor recurrence is increased when the tumor is larger than 1.2 in (3 cm) and the cancer has spread to the lymph nodes or surrounding tissue.

Alternatives

Depending on the medical condition, a **pancreas transplantation** may be considered as an alternative for some patients.

Diuretics

Definition

Diuretics are medicines that help reduce the amount of water in the body.

Purpose

Diuretics are used to treat the buildup of excess fluid in the body that occurs with some medical conditions such as **congestive heart failure**, **liver disease**, and **kidney disease**. Some diuretics are also prescribed to treat high blood pressure. These drugs act on the kidneys to increase urine output. This reduces the amount of fluid in the bloodstream, which in turn lowers blood pressure.

Description

There are several types of diuretics, also called water pills:

- Loop diuretics, such as bumetanide (Bumex) and furosemide (Lasix), get their name from the loop-shaped part of the kidneys where they have their effect.
- Thiazide diuretics include such commonly used diuretics as hydrochlorothiazide (HydroDIURIL, Esidrix), chlorothiazide (Diuril), and chlorthalidone (Hygroton).
- Potassium-sparing diuretics prevent the loss of potassium, which is a problem with other types of diuretics. Examples of potassium-sparing diuretics are amiloride (Midamor) and triamterene (Dyrenium).

In addition, some medicines contain combinations of two diuretics. The brands Dyazide and Maxzide, for example, contain the thiazide diuretic hydrochlorothiazide with the potassium-sparing diuretic triamterene.

Some nonprescription (over-the-counter) medicines contain diuretics. However, the medicines described here cannot be bought without a physician's prescription. They are available in tablet, capsule, liquid, and injectable forms.

Recommended dosage

The recommended dosage depends on the type of diuretic and may be different for different patients. Check with the physician who prescribed the drug or the pharmacist who filled the prescription for the correct dosage, and take the medicine exactly as directed.

Precautions

Seeing a physician regularly while taking a diuretic is important. The physician will check to make sure the medicine is working as it should and will watch for unwanted side effects.

Some people feel unusually tired when they first start taking diuretics. This effect usually becomes less noticeable over time, as the body adjusts to the medicine.

Because diuretics increase urine output, people who take this medicine may need to urinate more often, even during the night. Health care professionals can help patients schedule their doses to avoid interfering with their sleep or regular activities.

For patients taking the kinds of diuretics that rob potassium from the body, physicians may recommend adding potassium-rich foods or drinks, such as citrus fruits and juices, to the diet. Or they may suggest taking a potassium supplement or taking another medicine that keeps the body from losing too much potassium. If the physician recommends any of these measures, be sure to closely follow his or her directions. Do not make other diet changes without checking with the physician. People who are taking potassium-sparing diuretics should not add potassium to their **diets**, as too much potassium may be harmful.

People who take diuretics may lose too much water or potassium when they get sick, especially if they have severe **vomiting** and **diarrhea**. They should check with their physicians if they become ill.

These medicines make some people feel lightheaded, dizzy, or faint when they get up after sitting or lying down. Older people are especially likely to have this problem. Drinking alcohol, exercising, standing for long periods, or being in hot weather may make the problem worse. To lessen the problem, get up gradually and hold onto something for support if possible. Avoid drinking too much alcohol and be careful in hot weather or when exercising or standing for a long time.

Anyone who is taking a diuretic should be sure to tell the health care professional in charge before having surgical or dental procedures, medical tests, or emergency treatment.

Some diuretics make the skin more sensitive to sunlight. Even brief exposure to sun can cause a severe **sunburn**, **itching**, a rash, redness, or other changes in skin color. While being treated with this medicine, avoid being in direct sunlight, especially between 10 a.m. and 3 p.m.; wear a hat and tightly woven clothing that covers the arms and legs; use a sunscreen with a skin protection factor (SPF) of at least 15; protect the lips with a sun block lipstick; and do not use **tanning** beds, tanning booths, or sunlamps. People with fair skin may need to use a sunscreen with a higher skin protection factor.

Special conditions

People who have certain medical conditions or who are taking certain other medicines may have problems if they take diuretics. Before taking these drugs, be sure to let the physician know about any of these conditions:

ALLERGIES. Anyone who has had unusual reactions to diuretics or **sulfonamides** (sulfa drugs) in the past should let his or her physician know before using a diuretic. The physician should also be told about any **allergies** to foods, dyes, preservatives, or other substances.

PREGNANCY. Diuretics will not help the swelling of hands and feet that some women have during **pregnancy**. In general, pregnant women should not use diuretics unless a physician recommends their use. Although studies have not been done on pregnant women, studies of laboratory animals show that some diuretics can cause harmful effects when taken during pregnancy.

BREASTFEEDING. Some diuretics pass into breast milk, but no reports exist of problems in nursing babies whose mothers use this medicine. However, thiazide diuretics may decrease the flow of breast milk. Women who are **breastfeeding** and need to use a diuretic should check with their physicians.

OTHER MEDICAL CONDITIONS. Side effects of some diuretics may be more likely in people who have had a recent **heart attack** or who have liver disease or severe kidney disease. Other diuretics may not work properly in people with liver disease or severe kidney disease. Diuretics may worsen certain medical conditions, such as **gout**, **kidney stones**, **pancreatitis**, lupus erythematosus, and hearing problems. In addition, people with diabetes should be aware that diuretics may increase blood sugar levels. People with heart or blood vessel disease should know that some diuretics increase **cholesterol** or triglyceride levels. The risk of an allergic reaction to certain diuretics is greater in people with bronchial **asthma**. Before using diuretics, people with any of these medical problems should make sure their physicians are aware of their conditions. Also, people who have trouble urinating or who have high potassium levels in their blood may not be able to take diuretics and should check with a physician before using them.

WWW.BOOKBAZ.IR

KEY TERMS

Inflammation—Pain, redness, swelling, and heat that usually develop in response to injury or illness.

Lupus erythematosus—A chronic disease that affects the skin, joints, and certain internal organs.

Pancreas—A gland located beneath the stomach. The pancreas produces juices that help break down food.

Potassium—A mineral found in whole grains, meat, legumes, and some fruits and vegetables. Potassium is important for many body processes, including proper functioning of the nerves and muscles.

Triglyceride—A substance formed in the body from fat in the diet. Triglycerides are the main fatty materials in the blood. Together with protein, they make up high- and low-density lipoproteins (HDLs and LDLs). Triglyceride levels are important in the diagnosis and treatment of many diseases including high blood pressure, diabetes, and heart disease.

USE OF CERTAIN MEDICINES. Taking diuretics with certain other drugs may affect the way the drugs work or may increase the chance of side effects.

Side effects

Some side effects, such as loss of appetite, **nausea and vomiting**, stomach cramps, diarrhea, and **dizziness**, usually lessen or go away as the body adjusts to the medicine. These problems do not need medical attention unless they continue or interfere with normal activities.

Patients taking potassium-sparing diuretics should know the signs of too much potassium and should check with a physician as soon as possible if any of these symptoms occur:

- irregular heartbeat
- breathing problems
- numbness or tingling in the hands, feet, or lips
- confusion or nervousness
- unusual tiredness or weakness
- weak or heavy feeling in the legs

Patients taking diuretics that cause potassium loss should know the signs of too little potassium and should check with a physician as soon as possible if they have any of these symptoms:

- fast or irregular heartbeat
- weak pulse
- nausea or vomiting
- dry mouth
- excessive thirst
- muscle cramps or pain
- unusual tiredness or weakness
- mental or mood changes

Interactions

Diuretics may interact with other medicines. When this happens, the effects of one or both of the drugs may change or the risk of side effects may be greater. Anyone who takes a diuretic should let the physician know all other medicines he or she is taking and should ask whether the possible interactions can interfere with drug therapy. Among the drugs that may interact with diuretics are:

- Angiotensin-converting enzyme (ACE) inhibitors, such as benazepril (Lotensin), captopril (Capoten), and enalapril (Vasotec), used to treat high blood pressure. Taking these drugs with potassium-sparing diuretics may cause levels of potassium in the blood to be too high, increasing the chance of side effects.
- Cholesterol-lowering drugs such as cholestyramine (Questran) and colestipol (Colestid). Taking these drugs with combination diuretics such as Dyazide and Maxzide may keep the diuretic from working. Take the diuretic at least one hour before or four hours after the cholesterol-lowering drug.
- Cyclosporine (Sandimmune), a medicine that suppresses the immune system. Taking this medicine with potassium-sparing diuretics may increase the chance of side effects by causing levels of potassium in the blood to be too high.
- Potassium supplements, other medicines containing potassium, or salt substitutes that contain potassium. Taking these with potassium-sparing diuretics may lead to too much potassium in the blood, increasing the chance of side effects.
- Lithium, used to treat bipolar disorder (manic-depressive illness). Using this medicine with potassium-sparing diuretics may allow lithium to build up to poisonous levels in the body.
- Digitalis heart drugs, such as digoxin (Lanoxin). Using this medicine with combination diuretics such

as triamterene-hydrocholorthiazide (Dyazide, Maxzide) may cause blood levels of the heart medicine to be too high, making side effects such as changes in heartbeat more likely.

Always check with a physician or pharmacist before combining diuretics with any other prescription or nonprescription (over-the-counter) medicine.

Nancy Ross-Flanigan

Diverticulitis *see* **Diverticulosis and diverticulitis**

Diverticulosis and diverticulitis

Definition

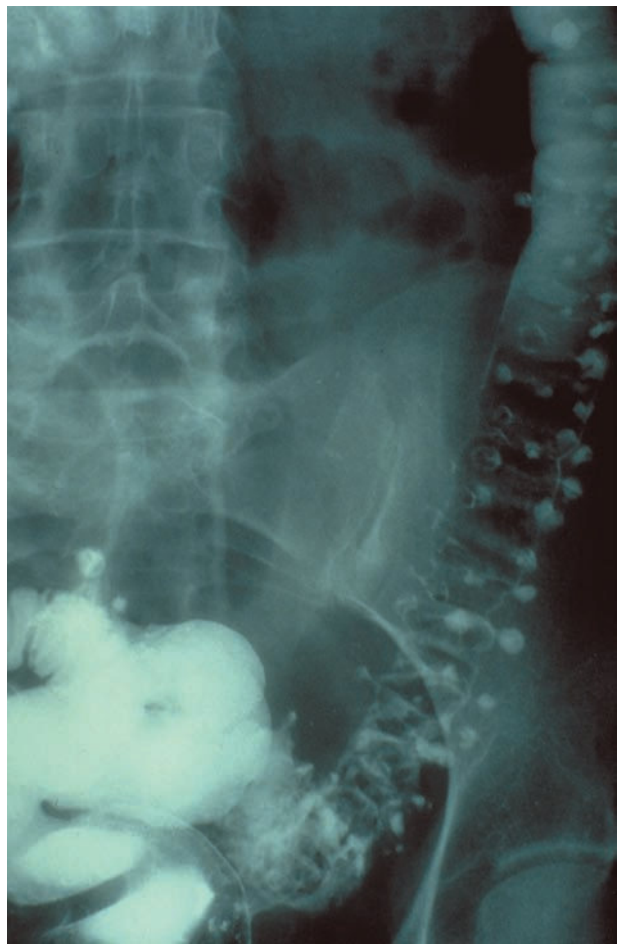
Diverticulosis refers to a condition in which the inner, lining layer of the large intestine (colon) bulges out (herniates) through the outer, muscular layer. These outpouchings are called diverticula. Diverticulitis refers to the development of inflammation and infection in one or more diverticula.

Description

Diverticula tend to occur most frequently in the last segment of the large intestine, the sigmoid colon. They occur with decreasing frequency as one examines further back toward the beginning of the large intestine. The chance of developing diverticula increases with age, so that by the age of 50, about 20–50% of all people will have some diverticula. By the age of 90, virtually everyone will have developed some diverticula. Most diverticula measure about 0.1 in (3 mm) to just over 1 in (3 cm) in diameter. Larger diverticula, termed giant diverticula, are quite infrequent, but may measure as large as 6 in (15 mm) in diameter.

Causes and symptoms

Diverticula are believed to be caused by overly forceful contractions of the muscular wall of the large intestine. As areas of this wall spasm, they become weaker and weaker, allowing the inner lining to bulge through. The anatomically weakest areas of the intestinal wall occur next to blood vessels which course through the wall, so diverticula commonly occur in this location.



A barium study x ray showing colonic diverticulosis. *(Custom Medical Stock Photo, Inc.)*

Diverticula are most common in the developed countries of the West (North America, Great Britain, northern and western Europe). This is thought to be due to the diet of these countries, which tends to be quite low in fiber. A diet low in fiber results in the production of smaller volumes of stool. In order to move this smaller stool along the colon and out of the rectum, the colon must narrow itself significantly, and does so by contracting down forcefully. This causes an increase in pressure, which, over time, weakens the muscular wall of the intestine and allows diverticular pockets to develop.

The origin of giant diverticula development is not completely understood, although one theory involves gas repeatedly entering and becoming trapped in an already-existing diverticulum, causing stretching and expansion of that diverticulum.

The great majority of people with diverticulosis will remain symptom-free. Many diverticula are quite

WWW.BOOKBAZ.IR

accidentally discovered during examinations for other conditions of the intestinal tract.

Some people with diverticulosis have symptoms such as **constipation**, cramping, and bloating. It is unclear whether these symptoms are actually caused by the diverticula themselves, or whether some other gastrointestinal condition (such as **irritable bowel syndrome**) might be responsible. A complication of diverticulosis occurs because many diverticula develop in areas very near blood vessels. Therefore, one serious risk of diverticulosis involves bleeding. Although an infrequent complication, the bleeding can be quite severe. Seventy-five percent of such bleeding episodes occur due to diverticula located on the right side of the colon. About 50% of the time, such bleeding will stop on its own.

One of the most common and potentially serious complications of diverticulosis is inflammation and infection of a particular diverticulum, called diverticulitis.

Diverticulitis is three times more likely to occur in the left side of the large intestine. Since most diverticula are located in the sigmoid colon (the final segment of the large intestine which empties into the rectum), most diverticulitis also takes place in the sigmoid. The elderly have the most serious complications from diverticulitis, although very severe infections can also occur in patients under the age of 50. Men are three times as likely as women to be stricken with diverticulitis.

Diverticulitis is believed to occur when a hardened piece of stool, undigested food, and bacteria (called a fecalith) becomes lodged in a diverticulum. This blockage interferes with the blood supply to the area, and infection sets in.

An individual with diverticulitis will experience **pain** (especially in the lower left side of the abdomen) and **fever**. In response to the infection and the irritation of nearby tissues within the abdomen, the abdominal muscles may begin to spasm. About 25% of all patients with diverticulitis will have some rectal bleeding, although this rarely becomes severe. Walled-off pockets of infection, called abscesses, may appear within the wall of the intestine, or even on the exterior surface of the intestine. When a diverticulum weakens sufficiently, and is filled to bulging with infected pus, a perforation in the intestinal wall may develop. When the infected contents of the intestine spill out into the abdomen, the severe infection called **peritonitis** may occur. Peritonitis is an infection and inflammation of the lining of the abdominal cavity, the peritoneum. Other complications of diverticulitis include the formation of abnormal connections between two organs that normally do not connect (fistulas; for example, the intestine and the bladder), and scarring outside of the intestine which squeezes off a portion of the intestine, obstructing it.

Diagnosis

The majority of diverticula do not cause any symptoms, and are often found by coincidence during an examination being performed for some other medical condition.

When diverticula are suspected because a patient begins to have sudden rectal bleeding, the location of the bleeding can be studied by performing an **angiography**. Angiography involves inserting a tiny tube through an artery in the leg, and moving it up into one of the major arteries of the gastrointestinal system. A particular chemical (contrast medium) which will show up on x-ray films is injected, and the area of bleeding is located by looking for an area where the contrast is leaking into the interior (lumen) of the intestine.

A procedure called **endoscopy** provides another method for examining the colon and locating the site of bleeding. In endoscopy, a small, flexible scope (endoscope) is inserted through the rectum and into the intestine. The scope usually bears a fiber-optic camera, which allows the view through this endoscope to be projected onto a television screen. The operator can introduce the endoscope further and further through the intestine to find the location of the bleeding.

Diagnosis of diverticulitis is not difficult in patients with previously diagnosed diverticulosis. The presence of abdominal pain and fever in such an individual would make the suspicion of diverticulitis quite high. Examination of the abdomen will usually reveal tenderness to touch, with the patient's abdominal muscles contracting strongly to protect the tender area. During a rectal exam (performed by inserting a finger into the rectum), a doctor may be able to feel an abnormal mass. Touching this mass may prove painful to the patient.

When a practitioner is suspicious of diverticulitis as the cause for the patient's symptoms, he or she will most likely avoid the types of tests usually used to diagnose gastrointestinal disorders. These include **barium enema** and endoscopy. The concern is that the increased pressure exerted on the intestine during these exams may increase the likelihood of intestinal perforation. After medical treatment for the

diverticulitis, these examinations may be performed in order to learn the extent of the patient's disease.

Treatment

Only about 20% of patients with diverticulosis ever have symptoms that lead them to seek medical help. Most people never know that they have diverticula. For those individuals who have cramping pain and constipation believed to be due to diverticulosis, the usual prescription involves increasing the fiber in the diet. This can be done by adding special diet supplements of bran or psyllium seed, which increase stool volume. Bleeding diverticula can usually be treated by bed rest, with blood **transfusion** needed for more severe bleeding (hemorrhaging). In cases of very heavy hemorrhaging, medications that encourage clotting can be injected during the course of a diagnostic angiography.

While there are almost no situations when uncomplicated diverticulosis requires surgery, giant diverticula always require removal. This is due to the very high chance of infection and perforation of these diverticula. When giant diverticula are diagnosed, the usual treatment involves removing that portion of the intestine.

Treatment for uncomplicated diverticulitis usually requires hospitalization. "Resting the bowel" is a mainstay of treatment, and involves keeping the patient from eating or sometimes even drinking anything by mouth. Therefore, the patient will need to receive fluids through a needle in the vein (intravenous or IV fluids). **Antibiotics** will also be administered through the IV. Some physicians will agree to try treatment at home for very mildly ill patients. These patients will be put on a liquid diet and receive oral antibiotics.

The various complications of diverticulitis need to be treated aggressively, because the death rate from such things as perforation and peritonitis is quite high. Abscesses can be drained of their infected contents by inserting a needle through the skin of the abdomen and into the **abscess**. When this is unsuccessful, open abdominal surgery will be required to remove the piece of the intestine containing the abscess. Fistulas require surgical repair, including the removal of the length of intestine containing the origin of the **fistula**, followed by immediate reconnection of the two free ends of intestine. Peritonitis requires open surgery. The entire abdominal cavity is cleaned by being irrigated (washed) with a warmed sterile saltwater solution, and the damaged piece of intestine is removed. Obstructions require immediate surgery to prevent perforation. Massive, uncontrollable bleeding, while rare, may require removal of part or all of the large intestine.

During any of these types of operations, the surgeon must make an important decision regarding the quantity of intestine which must be removed. When the amount of intestine removed is great, it may be necessary to perform a **colostomy**. A colostomy involves pulling the end of the remaining intestine through the abdominal wall, to the outside. This bit of intestine is then fashioned so that a bag can be fit over it. The patient's waste (feces) collect in the bag, because the intestine no longer connects with the rectum. This colostomy may be temporary, in which case another operation will be required to reconnect the intestine, after some months of substantial healing has occurred. Other times, the colostomy will need to be permanent, and the patient will have to adjust to living permanently with the colostomy bag. Most people with colostomies are able to go on with a very active life.

Occasionally, a patient will have such severe diverticular disease that a surgeon recommends planning ahead, and schedules removal of a portion of the colon. This is done to avoid the high risk of surgery performed after a complication has set in. Certain developments in a patient will identify those patients who are at very high risk of experiencing dangerous complications. Such elective surgery may be recommended:

- when an older individual has had several attacks of diverticulitis
- when someone under the age of 50 has had even one attack
- when treatment does not get rid of a painful mass
- when the intestine appears to be narrowing on x-ray examination (this could suggest the presence of cancer)
- when certain patients begin to regularly experience painful urination or urinary infections (this suggests that there may be a connection between the intestine and the bladder)
- when there is any question of cancer
- when the diverticular disease appears to be progressing rapidly

Prognosis

The prognosis for people with diverticula is excellent, with only 20% of such patients ever seeking any medical help for their condition.

While diverticulitis can be a difficult and painful disease, it is usually quite treatable. Prognosis is worse

WWW.BOOKBAZ.IR

KEY TERMS

Angiography—An x-ray study of the arteries in a particular part of the body. Angiography is often performed in order to localize internal bleeding.

Bowel obstruction—A blockage in the intestine that prevents the normal flow of waste down the length of the intestine.

Colostomy—A procedure performed when a large quantity of intestine is removed. The end piece of the intestine leading to the rectum is closed.

Diverticula—Outpouchings in the large intestine caused when the inner, lining layer of the large intestine (colon) bulges out (herniates) through the outer, muscular layer.

Endoscopy—Examination of an area of the gastrointestinal tract by putting a lighted scope, usually bearing a fiber-optic camera, into the rectum, and passing it through the intestine.

Fistula—An abnormal connection formed between two organs that usually have no connection whatsoever.

Sigmoid colon—The final portion of the large intestine that empties into the rectum.

for individuals who have other medical problems, particularly those requiring the use of steroid medications, which increase the chances of developing a serious infection. Prognosis is also worse in the elderly.

Prevention

While there is no absolutely certain way to prevent the development of diverticula, it is believed that high-fiber **diets** are of help. Foods that are recommended for their high fiber content include whole grain breads and cereals, and all types of fruits and vegetables. Most experts suggest that individuals take in about 0.71–1.23 oz (20–35 g) of fiber daily. If this is not possible to achieve through a person's diet, there are fiber products which can be mixed into 8 oz (237 mL) of water or juice, and which provide about 0.13–19 oz (4–6 g) of fiber.

Rosalyn Carson-DeWitt, MD

Dizziness

Definition

As a disorder, dizziness is classified into three categories—vertigo, syncope, and nonsyncope nonvertigo. Each category has a characteristic set of symptoms, all related to the sense of balance. In general, syncope is defined by a brief loss of consciousness (**fainting**) or by dimmed vision and feeling uncoordinated, confused, and lightheaded. Many people experience a sensation like syncope when they stand up too fast. Vertigo is the feeling that either the individual or the surroundings are spinning. This sensation is like being on a spinning amusement park ride. Individuals with nonsyncope nonvertigo dizziness feel as though they cannot keep their balance. This feeling may become worse with movement.

Description

The brain coordinates information from the eyes, the inner ear, and the body's senses to maintain balance. If any of these information sources is disrupted, the brain may not be able to compensate. For example, people sometimes experience **motion sickness** because the information from their body tells the brain that they are sitting still, but information from the eyes indicates that they are moving. The messages do not correspond and dizziness results.

Vision and the body's senses are the most important systems for maintaining balance, but problems in the inner ear are the most frequent cause of dizziness. The inner ear, also called the vestibular system, contains fluid that helps fine tune the information the brain receives from the eyes and the body. When fluid volume or pressure in one inner ear changes, information about balance is altered. The discrepancy gives conflicting messages to the brain about balance and induces dizziness.

Certain medical conditions can cause dizziness, because they affect the systems that maintain balance. For example, the inner ear is very sensitive to changes

in blood flow. Because medical conditions such as high blood pressure or low blood sugar can affect blood flow, these conditions are frequently accompanied by dizziness. Circulation disorders are the most common causes of dizziness. Other causes are **head injury**, ear infection, **allergies**, and nervous system disorders.

Dizziness often disappears without treatment or with treatment of the underlying problem, but it can be long term or chronic. According to the National Institutes of Health, 42% of Americans will seek medical help for dizziness at some point in their lives. The costs may exceed a billion dollars and account for five million doctor visits annually. Episodes of dizziness increase with age. Among people aged 75 or older, dizziness is the most frequent reason for seeing a doctor.

Causes and symptoms

Careful attention to symptoms can help determine the underlying cause of the dizziness. Underlying problems may be benign and easily treated or they may be dangerous and in need of intensive therapy. Not all cases of dizziness can be linked to a specific cause. More than one type of dizziness can be experienced at the same time and symptoms may be mixed. Episodes of dizziness may last for a few seconds or for days. The length of an episode is related to the underlying cause.

The symptoms of syncope include dimmed vision, loss of coordination, confusion, lightheadedness, and sweating. These symptoms can lead to a brief loss of consciousness or fainting. They are related to a reduced flow of blood to the brain; they often occur when a person is standing up and can be relieved by sitting or lying down. Vertigo is characterized by a sensation of spinning or turning, accompanied by nausea, **vomiting**, ringing in the ears, **headache**, or **fatigue**. An individual may have trouble walking, remaining coordinated, or keeping balance. Nonsyncope nonvertigo dizziness is characterized by a feeling of being off balance that becomes worse if the individual tries moving or performing detail-intense tasks.

A person may experience dizziness for many reasons. Syncope is associated with low blood pressure, heart problems, and disorders in the autonomic nervous system, the system of involuntary functions such as breathing. Syncope may also arise from emotional distress, **pain**, and other reactions to outside stressors. Nonsyncope nonvertigo dizziness may be caused by rapid breathing, low blood sugar, or **migraine headache**, as well as by more serious medical conditions.

Vertigo is often associated with inner ear problems called vestibular disorders. A particularly intense vestibular disorder, Ménière's disease, interferes with the volume of fluid in the inner ear. This disease, which affects approximately one in every 1,000 people, causes intermittent vertigo over the course of weeks, months, or years. Ménière's disease is often accompanied by ringing or buzzing in the ear, **hearing loss**, and a feeling that the ear is blocked. Damage to the nerve that leads from the ear to the brain can also cause vertigo. Such damage can result from head injury or a tumor. An **acoustic neuroma**, for example, is a benign tumor that wraps around the nerve. Vertigo can also be caused by disorders of the central nervous system and the cirulatory system, such as hardening of the arteries (arteriosclerosis), **stroke**, or **multiple sclerosis**.

Some medications cause changes in blood pressure or blood flow. These medications can cause dizziness in some people. Prescription medications carry warnings of such side effects, but common drugs, such as **caffeine** or nicotine, can also cause dizziness. Certain **antibiotics** can damage the inner ear and cause hearing loss and dizziness.

Diet may cause dizziness. The role of diet may be direct, as through alcohol intake. It may be also be indirect, as through arteriosclerosis caused by a high-fat diet. Some people experience a slight dip in blood sugar and mild dizziness if they miss a meal, but this condition is rarely dangerous unless the person is diabetic. Food sensitivities or allergies can also be a cause of dizziness. Chronic conditions, such as **heart disease**, and serious acute problems, such as seizures and strokes, can cause dizziness. However, such conditions usually exhibit other characteristic symptoms.

Diagnosis

During the initial medical examination, an individual with dizziness should provide a detailed description of the type of dizziness experienced, when it occurs, and how often each episode lasts. A diary of symptoms may help track this information. Report any symptoms that accompany the dizziness, such as a ringing in the ear or nausea, any recent injury or infection, and any medication taken.

Blood pressure, pulse, respiration, and body temperature are checked, and the ear, nose, and throat are scrutinized. The sense of balance is assessed by moving the individual's head to various positions or by tilt-table testing. In tilt-table testing, the person lies on a table that can be shifted into different positions and reports any dizziness that occurs.

WWW.BOOKBAZ.IR

KEY TERMS

Acoustic neuroma—A benign tumor that grows on the nerve leading from the inner ear to the brain. As the tumor grows, it exerts pressure on the inner ear and causes severe vertigo.

Arteriosclerosis—Hardening of the arteries caused by high blood cholesterol and high blood pressure.

Autonomic nervous system—The part of the nervous system that controls involuntary functions such as breathing and heart beat.

Computed tomography (CT)—An imaging technique in which cross-sectional x rays of the body are compiled to create a three-dimensional image of the body's internal structures.

Electronystagmography—A method for measuring the electricity generated by eye movements. Electrodes are placed on the skin around the eye and the individual is subjected to a variety of stimuli so that the quality of eye movements can be assessed.

Magnetic resonance imaging (MRI)—An imaging technique that uses a large circular magnet and radio waves to generate signals from atoms in the body. These signals are used to construct images of internal structures.

Vestibular system—The area of the inner ear that helps maintain balance.

Further tests may be indicated by the initial examination. Hearing tests help assess ear damage. X rays, computed tomography scan (CT scan), and **magnetic resonance imaging** (MRI) can pinpoint evidence of nerve damage, tumor, or other structural problems. If a vestibular disorder is suspected, a technique called electronystagmography (ENG) may be used. ENG measures the electrical impulses generated by eye movements. Blood tests can determine diabetes, high **cholesterol**, and other diseases. In some cases, a heart evaluation may be useful. Despite thorough testing, an underlying cause cannot always be determined.

Treatment

Treatment is determined by the underlying cause. If an individual has a cold or **influenza**, a few days of bed rest is usually adequate to resolve dizziness. Other causes of dizziness, such as mild vestibular system damage, may resolve without medical treatment.

If dizziness continues, drug therapy may prove helpful. Because circulatory problems often cause dizziness, medication may be prescribed to control blood pressure or to treat arteriosclerosis. Sedatives may be useful to relieve the tension that can trigger or aggravate dizziness. Low blood sugar associated with diabetes sometimes causes dizziness and is treated by controlling blood sugar levels. An individual may be asked to avoid caffeine, nicotine, alcohol, and any substances that cause allergic reactions. A low-salt diet may also help some people.

When other measures have failed, surgery may be suggested to relieve pressure on the inner ear. If the dizziness is not treatable by drugs, surgery, or other means, **physical therapy** may be used and the patient may be taught coping mechanisms for the problem.

Alternatives

Because dizziness may arise from serious conditions, it is advisable to seek medical treatment. Alternative treatments can often be used alongside conventional medicine without conflict. Relaxation techniques, such as **yoga** and **massage therapy** that focus on relieving tension, are popularly recommended methods for reducing **stress**. Aromatherapists recommend a warm bath scented with essential oils of lavender, geranium, and sandalwood.

Homeopathic therapies can work very effectively for dizziness, and are especially applicable when no organic cause can be identified. An osteopath or chiropractor may suggest adjustments of the head, jaw, neck, and lower back to relieve pressure on the inner ear. Acupuncturists also offer some treatment options for acute and chronic cases of dizziness. Nutritionists may be able to offer advice and guidance in choosing dietary supplements, identifying foods to avoid, and balancing nutritional needs.

Prognosis

Outcome depends on the cause of dizziness. Controlling or curing the underlying factors usually relieves dizziness. In some cases, dizziness disappears without treatment. In a few cases, dizziness can become a permanent disabling condition and a person's options are limited.

Prevention

Most people learn through experience that certain activities will make them dizzy and they learn to avoid them. For example, if reading in a car produces motion sickness, an individual leaves reading materials for after the trip. Changes to the diet can also cut down on episodes of dizziness in susceptible people. Relaxation techniques can help ward off tension and **anxiety** that can cause dizziness.

These techniques can help minimize or even prevent dizziness for people with chronic diseases. For example, persons with Ménière's disease may avoid episodes of vertigo by leaving salt, alcohol, and caffeine out of their **diets**. Reducing blood cholesterol can help diminish arteriosclerosis and indirectly treat dizziness.

Some cases of dizziness cannot be prevented. Acoustic neuromas, for example, are not predictable or preventable. When the underlying cause of dizziness cannot be discovered, it may be difficult to recommend preventive measures. Alternative approaches designed to rebalance the body's energy flow, such as **acupuncture** and constitutional homeopathy, may be helpful in cases where the cause of dizziness cannot be pinpointed.

Do not resuscitate (DNR) order

Definition

A do not resuscitate (DNR) order is a kind of advanced medical directive allowed by a 1991 federal law. The law expanded the notion of patient autonomy to situations in which patients may not be able to make crucial medical decisions due to incapacitation. A DNR order instructs medical personnel not to perform life-saving **cardiopulmonary resuscitation** (CPR) or other procedures to restart the heart or breathing once it has ceased. By law, the DNR directive must be offered as an option to patients by health providers in and, in some states, outside a hospital setting. Once signed, the DNR directive must be placed in the patient's chart.

Purpose

With such advanced cardiopulmonary techniques as CPR, it is possible in many cases to keep a patient's heart and lungs functioning, independent of how terminal or hopeless his or her medical condition becomes. The DNR program is designed to give people in the final stages of a terminal illness or those who are suffering from intractable pain the option for deciding against life-saving measures that may only prolong their pain and inevitable death. The option of deciding against life-saving measures is considered to be a formal part of patient autonomy and is respected as an ethical subset of medical informed consent.

Description

DNR orders affect a small group of patients and are designed to avoid the suffering of a terminal illness or other serious conditions that are medically irreversible. The order actually authorizes medical treatment to be withheld. It is included with the medical orders in the medical chart, and with it, hospital and pre-hospital personnel are restricted from using CPR techniques and other measures to revive the patient.

Some states allow DNR orders only in hospital settings. Other states allow DNR orders to be honored by emergency responders working outside the hospital setting. Over half of the states in the United States have pre-hospital DNR orders. A physician must sign the pre-hospital DNR directives. The state's emergency medical service (EMS) department or state medical association administers the programs. In some states, the DNR may be called a pre-hospital medical care directive or a comfort care-only document.

A DNR order can be revoked at any time in any way that effectively communicates the patient's desire. It can come from the patient in the form of a letter or document. It can come from the patient telling an emergency provider to disregard the order. The revocation can be invoked by removing any bracelet or medallion that indicates DNR status. It can be communicated by the designated health agent or patient

WWW.BOOKBAZ.IR

KEY TERMS

Advanced medical directive—A legal document drafted by a patient, in advance, ordering specific medical procedures to be offered or withheld if they are incapacitated.

Cardiopulmonary resuscitation (CPR)—A set of medical procedures used in an emergency to restart the heart and lungs.

Medical agent—A designated representative for the patient who, in advance, is legally empowered to carry out their wishes with respect to medial care.

Medical surrogate—Another name for a medical agent or person legally designated to represent the patient with medical providers.

representative who has the power to express the patient's wishes to health providers. Some states maintain a registry for individuals with DNR orders. It is important to find out about a state's service for DNR and its particular legal forms and requirements.

Legal requirements

DNR law varies from state to state, but there are some common features. The DNR must be signed by a physician before responders or other providers may honor it. Once in effect, DNR orders include only certain life-preserving procedures, like CPR; physicians will not withhold comfort treatment or pain alleviation. If a physician or other provider is unable or are unwilling to carry out the order (for moral or professional reasons), he or she is required to transfer the care of the patient to a provider who will.

Preparation

Do not resuscitate orders are a part of advanced medical directives. Advance directives are legal documents that place limits on medical treatment, guide medical providers on the wishes and options of the patient, and help family members and providers make decisions in accordance with the patient's wishes. Advance directives are prepared in advance and may include a living will that details the patient's wishes should he or she become incapacitated. A DNR order is a very specific order that medical treatment be withheld, especially CPR. Finally, a medical agent or a person with a durable medical power of attorney is usually appointed to carry out all wishes of the patient and to make sure that specific wishes, like DNR, are honored.

An advanced directive for withholding resuscitation can be prepared by requesting a form from the physician, by writing down that wish, by having a lawyer draft a living will, or by using computer software for legal documents. States differ in the respect of whether the documents must be cosigned or notarized. Crucial to the effort is that the physician be told of the wishes of the patient.

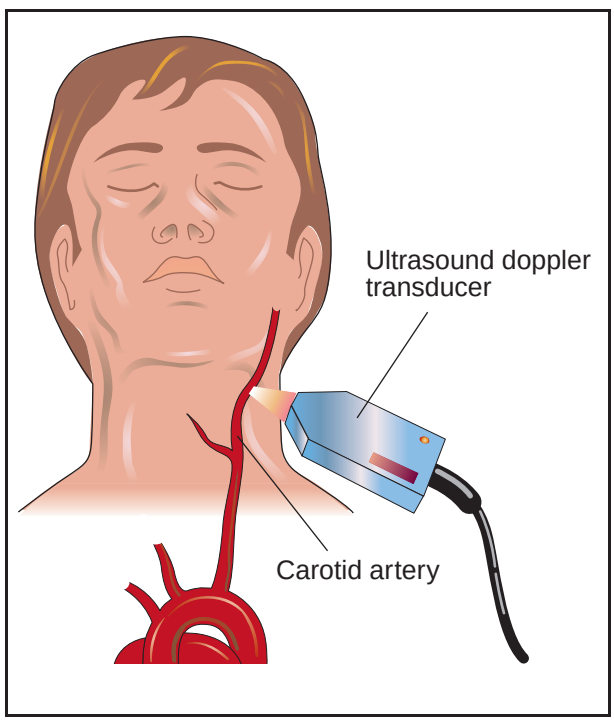
Doppler ultrasonography

Definition

Doppler ultrasonography is a non-invasive diagnostic procedure that changes sound waves into an image that can be viewed on a monitor.

Purpose

Doppler ultrasonography can detect the direction, velocity, and turbulence of blood flow. It is frequently used to detect problems with heart valves or to measure blood flow through the arteries. Specifically, it is useful in the work up of **stroke** patients, in assessing blood flow in the abdomen or legs, and in viewing the heart to monitor carotid artery diseases.



Doppler ultrasonography can detect the direction, velocity, and turbulence of blood flow. Because it is non-invasive and uses no x rays, Doppler ultrasonography is widely used for numerous diagnostic procedures. *(Illustration by Electronic Illustrators Group. © Cengage Learning®.)*

Precautions

The test is widely used because it is noninvasive, uses no x rays, and gives excellent images. It is harmless, painless, and widely available.

Description

Doppler ultrasonography makes use of two different principles. The **ultrasound** principle is this: when a high-frequency sound is produced and aimed at a target, it will be reflected by its target and the reflected sound can be detected back at its origin. In addition, it is known that certain crystals (called piezoelectric crystals) produce an electrical pulse when vibrated by a returning sound.

The Doppler principle is simply that sound pitch increases as the source moves toward the listener and decreases as it moves away.

Medical science utilizes these two principles in the following way. A transducer (sometimes called a probe) containing piezoelectric crystals sends a series of short sound pulses into the body and pauses between each pulse to listen for the returning sounds. The machine then determines the direction and depth of each returning sound and coverts this into a point of light on a television monitor. Thousands of these pulses are computed and displayed every second to produce an image of the organ being studied. The image allows the doctor to see the organ functioning in real time.

The newest addition to this test is the addition of color. Adding color to the image shows the direction and rate of blood flow more clearly.

During a Doppler ultrasonography procedure the technician will apply a gel to the skin, then place the transducer against the skin at various angles. The transducer sends the information it receives to a television monitor that shows a moving image of the organ being studied. The technician can save these images either on video tape, paper, or x-ray film for further study.

Preparation

There is no special preparation needed for this test. The ultrasound technician may apply a clear gel to the skin in order to help the transducer more freely over the body.

WWW.BOOKBAZ.IR

KEY TERMS

Doppler effect—The principle that the sound of an object moving toward you has a higher pitch than the sound when it is moving away from you.

Transducer—The part of a machine that changes signals in one form into another form.

Ultrasound—Sound that is too high for the human ear to hear.

Aftercare

No aftercare is necessary.

Results

A Doppler ultrasonography test showing no restricted blood flow is a normal finding.

Abnormal results

Disrupted or obstructed blood flow through the neck arteries may indicate the person is a risk of having a stroke. (Narrowed arterial flow in the legs does not necessarily indicate a risk of stroke.)

Dorothy Elinor Stonely

Down syndrome

Definition

Down syndrome is the most common chromosome disorder and genetic cause of **intellectual disability**. It occurs because of the presence of an extra copy of chromosome 21. For this reason, it is also called trisomy 21.

Demographics

As of 2014, the Centers for Disease Control (CDC) estimate that each year about 6,000 babies in the United States are born with Down syndrome. In other words, about 1 of every 700 babies born in the United States each year is born with Down syndrome. It affects an equal number of male and female babies. The majority of cases of Down syndrome occur due to an extra chromosome 21 within the egg cell supplied by the mother (nondisjunction).

Down syndrome occurs with equal frequency across all ethnic groups and subpopulations.

Description

Named after John Langdon Down, the first physician to identify the syndrome, Down syndrome is the result of genetic variations. When the reproductive cells, the sperm and ovum, combine at fertilization, the fertilized egg that results contains 23 chromosome pairs. A normal fertilized egg that will develop into a female contains chromosome pairs 1 through 22, and the XX pair. A normal fertilized egg that will develop into a male contains chromosome pairs 1 through 22, and the XY pair. When the fertilized egg contains extra material from chromosome number 21, this results in Down syndrome. This event is called nondisjunction and it occurs in 95% of Down syndrome cases. The baby therefore receives an extra chromosome at conception. Because of this extra chromosome 21, individuals affected with Down syndrome have 47 instead of 46 chromosomes. This additional genetic material disrupts the normal course of development, causing the characteristic features of Down syndrome.

Risk factors

Parents who already have a baby with Down syndrome or who have abnormalities in their own chromosome 21 are at higher risk for having a baby with Down syndrome. The chance of having a baby with Down syndrome also increases as a woman gets older. As a woman's age (maternal age) increases, the risk of having a Down syndrome baby increases significantly. By the time the woman is age 35, the risk increases to one in 400; by age 40 the risk increases to one in 110; and, by age 45, the risk becomes one in 35. There is no increased risk of either mosaicism or translocation with increased maternal age.

Causes and symptoms

Down syndrome is a chromosomal disorder caused by an error in cell division that results in the presence of an additional third chromosome 21. In approximately 1–2% of Down syndrome cases, the original egg and sperm cells contain the correct number of chromosomes, 23 each. The problem occurs sometime shortly after fertilization—during the phase when cells are dividing rapidly. One cell divides abnormally, creating a line of cells with an extra copy of chromosome 21. This form of genetic disorder is

called mosaicism. The individual with this type of Down syndrome has two types of cells: those with 46 chromosomes (the normal number), and those with 47 chromosomes (as occurs in Down syndrome). Individuals affected with this mosaic form of Down syndrome generally have less severe signs and symptoms of the disorder.

Another relatively rare genetic accident that causes Down syndrome is called translocation. During cell division, chromosome 21 somehow breaks. The broken off piece of this chromosome then becomes attached to another chromosome. Each cell still has 46 chromosomes, but the extra piece of chromosome 21 results in the signs and symptoms of Down syndrome. Translocations occur in about 3–4% of cases of Down syndrome.

While Down syndrome is a chromosomal disorder, a baby is usually identified at birth through observation of a set of common physical characteristics. Not all affected babies will exhibit all of the symptoms discussed. There is a large variability in the number and severity of these characteristics from one affected individual to the next. Babies with Down syndrome tend to be overly quiet, less responsive to stimuli, and have weak, floppy muscles. A number of physical signs may also be present. These include: a flat appearing face; a small head; a flat bridge of the nose; a smaller than normal, low-set nose; small mouth, which causes the tongue to stick out and to appear overly large; upward slanting eyes; bright speckles on the iris of the eye (Brushfield spots); extra folds of skin located at the inside corner of each eye near the nose (epicanthal folds); rounded cheeks; small, misshapen ears; small, wide hands; an unusual deep crease across the center of the palm (simian crease); an inwardly curved little finger; a wide space between the great and the second toes; unusual creases on the soles of the feet; overly flexible joints (sometimes referred to as being double-jointed); and shorter-than-normal stature.

Other types of defects often accompany Down syndrome. Approximately 30–50% of all children with Down syndrome are found to have heart defects. A number of different heart defects are common in Down syndrome. All of these result in abnormal patterns of blood flow within the heart. Abnormal blood flow within the heart often means that less oxygen is sent into circulation throughout the body, which can cause **fatigue**, a lack of energy, and poor muscle tone.

Malformations of the gastrointestinal tract are present in about 5–7% of children with Down syndrome. The most common malformation is a narrowed, obstructed duodenum (the part of the intestine into which the stomach empties). This disorder, called duodenal atresia, interferes with the baby's milk or formula leaving the stomach and entering the intestine for digestion. The baby often vomits forcibly after feeding, and cannot gain weight appropriately until the defect is repaired.

Another malformation of the gastrointestinal tract that is seen in patients with Down syndrome is an abnormal connection between the windpipe (trachea) and the digestive tube of the throat (esophagus) called a tracheo-esophageal **fistula** (T-E fistula). This connection interferes with eating and/or breathing because it allows air to enter the digestive system and/or food to enter the airway.

Other medical conditions occurring in patients with Down syndrome include an increased chance of developing infections, especially ear infections and **pneumonia**; certain kidney disorders; thyroid disease (especially low or hypothyroid); **hearing loss**; vision impairment requiring glasses (corrective lenses); and a 20 times greater chance than the population as a whole of developing leukemia.

Development in a baby and child affected with Down syndrome occurs at a much slower than normal rate. Because of weak, floppy muscles (hypotonia), babies learn to sit up, crawl, and walk much later than their unaffected peers. Talking is also quite delayed. The level of intellectual disability is considered to be mild-to-moderate in Down syndrome, but it varies a great deal from one child to the next. While it is impossible to predict the severity of Down syndrome at birth, with proper education, children who have Down syndrome are capable of learning. Most children affected with Down syndrome can read and write and are placed in special education classes in school. The majority of individuals with Down syndrome become semi-independent adults, meaning that they can take care of their own needs with some assistance.

As people with Down syndrome age, they face an increased chance of developing the brain disease called Alzheimer's (sometimes referred to as **dementia** or senility). Most people have a 12% chance of developing Alzheimer's, but almost all people with Down syndrome will have either **Alzheimer's disease** or a similar type of dementia by the age of 50. Alzheimer disease causes the brain to shrink and to break down. The number of brain cells decreases, and abnormal deposits and structural arrangements occur. This process results in a loss of brain functioning. People with Alzheimer's have strikingly faulty memories. Over time, people with Alzheimer's disease will lapse into an increasingly unresponsive state.

As people with Down syndrome age, they also have an increased chance of developing a number of

WWW.BOOKBAZ.IR

KEY TERMS

Chromosome—A microscopic thread-like structure found within each cell of the body and consists of a complex of proteins and DNA. Humans have 46 chromosomes arranged into 23 pairs. Changes in either the total number of chromosomes or their shape and size (structure) may lead to physical or mental abnormalities.

Intellectual disability—Significant impairment in intellectual function and adaptation in society. Usually associated an intelligence quotient (IQ) below 70.

Karyotype—A standard arrangement of photographic or computer-generated images of chromosome pairs from a cell in ascending numerical order, from largest to smallest.

Mosaic—A term referring to a genetic situation in which an individual's cells do not have the exact same composition of chromosomes. In Down syndrome, this may mean that some of the individual's cells have a normal 46 chromosomes, while other cells have an abnormal 47 chromosomes.

Nondisjunction—Non-separation of a chromosome pair, during either meiosis or mitosis.

Translocation—The transfer of one part of a chromosome to another chromosome during cell division. A balanced translocation occurs when pieces from two different chromosomes exchange places without loss or gain of any chromosome material. An unbalanced translocation involves the unequal loss or gain of genetic information between two chromosomes.

Trisomy—The condition of having three identical chromosomes, instead of the normal two, in a cell.

other illnesses, including **cataracts**, thyroid problems, diabetes, and seizure disorders.

Diagnosis

Examination

Diagnosis is usually suspected at birth, when the characteristic physical signs of Down syndrome are observed.

Tests

Once Down syndrome is suspected, **genetic testing** (chromosome analysis) can be undertaken in order to verify the presence of the disorder. This testing is usually done on a blood sample, although chromosome analysis can also be done on other types of tissue, including the skin. The cells to be studied are prepared in a laboratory. Chemical stain is added to make the characteristics of the cells and the chromosomes stand out. Chemicals are added to prompt the cells to go through normal development, up to the point where the chromosomes are most visible, prior to cell division. At this point, they are examined under a microscope and photographed. The photograph is used to sort the different sizes and shapes of chromosomes into pairs. In most cases of Down syndrome, one extra chromosome 21 will be revealed. The final result of such testing, with the photographed chromosomes paired and organized by shape and size, is called the individual's karyotype. An individual with Down syndrome will have a 47 XX + 21 karyotype if they are female and a 47 XY + 21 karyotype if they are male.

Women who become pregnant after the age of 35 are offered prenatal tests to determine whether or not their developing baby is affected with Down syndrome. A genetic counselor meets with these families to inform them of the risks and to discuss the types of tests available to make a diagnosis prior to delivery. Because there is a slight risk of **miscarriage** following some prenatal tests, all testing is optional, and couples need to decide whether or not they desire to take this risk in order to learn the status of their unborn baby.

Screening tests are used to estimate the chance that an individual woman will have a baby with Down syndrome. A test called the maternal serum **alpha-fetoprotein test** (MSAFP) is offered to all pregnant women under the age of 35. If the mother decides to have this test, it is performed between 15 and 22 weeks of **pregnancy**. The MSAFP screen measures a protein and two hormones that are normally found in maternal blood during pregnancy. A specific pattern of these hormones and protein can indicate an increased risk for having a baby born with Down syndrome. However, this is only a risk and MSAFP cannot diagnose Down syndrome directly. Women found to have an increased risk of their babies being affected with Down syndrome are offered **amniocentesis**. The MSAFP test can detect up to 60% of all babies who will be born with Down syndrome.

Ultrasound screening for Down syndrome is also available. This is generally performed in the mid-trimester of pregnancy. Abnormal growth patterns characteristic of Down syndrome such as growth retardation, heart defects, duodenal atresia, T-E fistula, shorter than normal long-bone lengths, and extra folds

of skin along the back of the neck of the developing fetus may all be observed via ultrasonic imaging.

The only way to definitively establish (with about 99% accuracy) the presence or absence of Down syndrome in a developing baby is to test tissue during the pregnancy itself. This is usually done either by amniocentesis, or **chorionic villus sampling** (CVS). All women under the age of 35 who show a high risk for having a baby affected with Down syndrome via an MSAFP screen and all mothers over the age of 35 are offered either CVS or amniocentesis. In CVS, a tiny tube is inserted into the opening of the uterus to retrieve a small sample of the placenta (the organ that attaches the growing baby to the mother via the umbilical cord, and provides oxygen and **nutrition**). In amniocentesis, a small amount of the fluid in which the baby is floating is withdrawn with a long, thin needle. CVS may be performed as early as 10–12 weeks into a pregnancy. Amniocentesis is generally not performed until at least the fifteenth week. Both CVS and amniocentesis carry small risks of miscarriage. Approximately 1% of women miscarry after undergoing CVS testing, while approximately 0.5% miscarry after undergoing amniocentesis. Both amniocentesis and CVS allow the baby's own karyotype to be determined.

Approximately 75% of all babies diagnosed prenatally as affected with Down syndrome do not survive to term and spontaneously miscarry. In addition, these prenatal tests can only diagnose Down syndrome, not the severity of the symptoms that the unborn child will experience. For this reason, a couple might use this information to begin to prepare for the arrival of a baby with Down syndrome, to terminate the pregnancy, or in the case of miscarriage or termination, decide whether to consider adoption as an alternative.

Treatment

Traditional

No treatment is available to cure Down syndrome. Treatment is directed at addressing the individual concerns of a particular patient. For example, heart defects may require surgical repair, as will duodenal atresia and T-E fistula. Many Down syndrome patients will need to wear glasses to correct vision. Patients with hearing impairment benefit from **hearing aids**.

While some decades ago all children with Down syndrome were quickly placed into institutions for lifelong care, research shows very clearly that the best outlook for children with Down syndrome is a normal family life in their own home. This requires careful support and education of the parents and the siblings. It is a life-changing event to learn that a new baby has a permanent condition that will affect essentially all aspects of his or her development. Some community groups help families deal with the emotional effects of raising a child with Down syndrome. Schools are required to provide services to children with Down syndrome, sometimes in separate special education classrooms, and sometimes in regular classrooms (this is called mainstreaming or inclusion).

As of May 2000, the genetic sequence for chromosome 21 was fully determined, which opens the door to new approaches to the treatment of Down syndrome through the development of gene-specific therapies.

Alternatives

Clinical trials for the treatment of Down syndrome are currently sponsored by the National Institutes of Health (NIH) and other agencies. In 2009, NIH reported 20 ongoing or recently completed studies.

A few examples include:

- The evaluation of a new prenatal blood test for Down syndrome. (NCT00877292)
- The evaluation of the efficacy on language and cognitive function in Down syndrome patients who take Rivastigmine. (NCT00748007)
- The evaluation of the efficacy and tolerability of Continuous Positive Pressure in case of SAOS by Down Syndrome patients. (NCT00394290)
- A study to assess whether memantine is effective and safe in preventing age related cognitive deterioration in people with Down's syndrome (DS) age 40 and over. (NCT00240760)

Clinical trial information is constantly updated by NIH and the most recent information on Down syndrome trials can be found at: http://clinicaltrials.gov/search/open/condition=%22Down+Syndrome%22.

Prognosis

The prognosis for an individual with Down syndrome is quite variable, depending on the types of complications (heart defects, susceptibility to infections, development of leukemia, etc.). The severity of the retardation can also vary significantly. Without the presence of heart defects, about 90% of children with Down syndrome live into their teens. People with Down syndrome appear to go through the normal physical changes of **aging** more rapidly, however.

WWW.BOOKBAZ.IR

The average age of death for an individual with Down syndrome is about 50 to 55 years.

Still, the prognosis for a baby born with Down syndrome is better than ever before. Because of modern medical treatments, including **antibiotics** to treat infections, and surgery to treat heart defects and duodenal atresia, life expectancy has greatly increased. Community and family support allows people with Down syndrome to have rich, meaningful relationships. Because of educational programs, some people with Down syndrome are able to hold jobs.

Prevention

There is no known way to prevent the Down syndrome. Women expecting to give birth can take steps before and during pregnancy to have a healthy pregnancy. Steps include taking a daily multivitamin with **folic acid** (400 mcg), not **smoking**, and not drinking alcohol during pregnancy. Once a couple has had one baby with Down syndrome, they are often concerned about the likelihood of future offspring also being born with the disorder.

When a baby with Down syndrome has the type that results from a translocation, it is possible that one of the two parents is a carrier of a balanced translocation. A carrier has rearranged chromosomal information and can pass it on, but he or she does not have an extra chromosome and is not affected with the disorder. When one parent is a carrier of a translocation, the chance of future offspring having Down syndrome is greatly increased. The specific risk will have to be assessed by a genetic counsellor. Approximately 60% of women with Down syndrome are fully capable of having children. The risk of a woman with trisomy 21 having a child affected with Down syndrome is 50%.

Drowning

Definition

Drowning is death due to submersion in liquid (usually water) long enough to prevent oxygenation of the blood. Near-drowning is the term for survival after suffocation caused by submersion in water or another fluid. Some experts classify as drowning those cases of temporary survival that end in death within 24 hours.

Description

Drowning remains a significant **public health** concern, as it is a major cause of disability and death. Drowning has been previously defined as death secondary to asphyxia while immersed in a liquid, usually water, or within 24 hours of submersion. Near-drowning occurs when the victim survives an immersive event.

Demographics

An estimated 4,086 drownings occur in the United States each year, making it the sixth most common cause of death. The typical victim is young and male. In children between the ages of one and four, drowning is the most common cause of death by injury. The number of near-drownings in the United States has not been delineated, as not all victims of these accidents seek medical care. However, emergency department records show that for every child death by drowning, there are about four emergency department visits for children injured in some type of submersive event. The highest drowning risk is in toddlers and teenagers, with boys making up 80% of drowning victims over a year of age. Nearly half of all drownings and near-drownings involve children less than four years old. Home swimming pools pose the greatest risk for children, being the site of 60–90% of drownings in the 0–4 age group. Teenage boys also face a heightened risk of drowning and near-drowning, largely because of their tendency to behave recklessly, and to use drugs and alcohol, which are implicated in 40–50% of teenage drownings.

There are clear-cut racial differences in drowning rates, probably due to access to effective swim and water safety classes. American Indian children have twice the rate of drowning deaths that white children have. African-American children (ages 5–14 years) and males have the highest rates of drowning, with three times as many African-American children drowning. African-American males ages 15–19 have the highest drowning rates of any group.

Many drownings associated with watercraft involve the use of ethanol. Alcohol intoxication has been implicated in about 30–50%percnet; of drownings in adults or adolescents in association with a boating or other watercraft accident.

Causes and symptoms

Many different circumstances may lead to drowning or near-drowning. On many occasions, near-drownings are secondary to an event such as a **heart attack** that causes unconsciousness, or a head or spinal injury that prevents a diver from resurfacing. Near-drownings, moreover, can occur in shallow as well as deep water. Small children have drowned or almost drowned in bathtubs, toilets, industrial-size cleaning buckets, and washing machines. Bathtubs are especially dangerous for infants six months to one year old, who can sit up straight in a bathtub but may lack the ability to pull themselves out of the water if they slip under the surface.

A reduced concentration of oxygen in the blood (hypoxemia) is common to all near-drownings. Human life depends on a constant supply of oxygen-laden air

WWW.BOOKBAZ.IR

reaching the blood by way of the lungs. When drowning begins, the larynx (the air passage in the throat) closes involuntarily, preventing both air and water from entering the lungs. In 10–15% of cases, hypoxemia results because the larynx stays closed. This is called "dry drowning." Hypoxemia also occurs in "wet drowning," the 85–90% of cases where the larynx relaxes and water enters the lungs. The physiological mechanisms that produce hypoxemia in wet drowning are different for freshwater and saltwater, but only a small amount of either kind of water is needed to damage the lungs and interfere with the body's oxygen intake. All of this happens very quickly: within three minutes of submersion most people are unconscious, and within five minutes the brain begins to suffer from lack of oxygen. Abnormal heart rhythms (cardiac dysrhythmias) often occur in near-drowning cases, and the heart may stop pumping (cardiac arrest). An increase in blood acidity (acidosis) is another consequence of near-drowning, and under some circumstances near-drowning can cause a substantial increase or decrease in the volume of circulating blood. Many victims experience a severe drop in body temperature (**hypothermia**). Hypothermia sometimes can have a protective effect on the brain, so survival after prolonged cold immersion is occasionally possible.

The signs and symptoms of near-drowning can differ widely from person to person. Some victims are alert but agitated, while others are comatose. Breathing may have stopped, or the victim may be gasping for breath. Bluish skin (**cyanosis**), coughing, and frothy pink sputum (material expelled from the respiratory tract by coughing) are often observed. Rapid breathing (tachypnea), a rapid heart rate (tachycardia), and a low-grade **fever** are common during the first few hours after rescue. Conscious victims may appear confused, lethargic, or irritable.

Diagnosis

Diagnosis relies on a **physical examination** of the victim and on a wide range of tests and other procedures. Blood is taken to measure oxygen levels and for many other purposes. Pulse oximetry, another way of assessing oxygen levels, involves attaching a device called a pulse oximeter to the patient's finger. An electrocardiograph is used to monitor heart activity. X rays and CT scans can detect head and neck injuries and excess tissue fluid (**edema**) in the lungs.

Treatment

Treatment begins with removing the victim from the water and performing **cardiopulmonary resuscitation** (CPR) if there is no breathing or pulse. One purpose of CPR is to bring oxygen to the lungs, heart, brain, and other organs by breathing into the victim's mouth. When the victim's heart has stopped, CPR also attempts to get the heart pumping again by pressing down on the victim's chest. Oxygen is administered to the victim as soon as possible. If the victim's breathing has stopped or is otherwise impaired, emergency personnel insert a tube into the windpipe (trachea) to maintain the airway (this is called endotracheal intubation). The victim is also checked for head, neck, and other injuries, and fluids are given intravenously. Hypothermia victims require careful handling to protect the heart from developing abnormal rhythms.

In the emergency department, victims continue receiving oxygen until blood tests show a return to normal. About one-third are intubated and initially need mechanical support to breathe. Rewarming is undertaken when hypothermia is present. Victims may arrive needing treatment for cardiac arrest or cardiac dysrhythmias. Comatose patients present a special problem: although various treatment approaches have been tried, none have proved beneficial. In the mildest cases, patients can be discharged from the emergency department after four to six hours if their blood oxygen level is normal and no signs or symptoms of near-drowning are present. But because lung problems can arise 12 or more hours after submersion, the medical staff must first be satisfied that the patients are willing and able to seek further medical help if necessary. Admission to a hospital for at least 24 hours for further observation and treatment is a must for patients who do not appear to recover fully in the emergency department.

Prognosis

Neurological damage is the major long-term concern in the treatment of near-drowning victims. Patients who arrive at an emergency department awake and alert usually survive with brain function intact, as do about 90% of those who arrive mentally impaired (lethargic, confused, and so forth) but not comatose. Death or permanent neurological damage is very likely when patients arrive comatose. Early rescue of near-drowning victims (within five minutes of submersion) and prompt CPR (within less than 10 minutes of submersion) seem to be the best guarantees of a complete recovery. An analysis of 715 patients admitted to emergency departments in 1971–81 revealed that 69% recovered completely, 25% died, and 6% survived but had permanent neurological damage.

Prevention

Prevention depends on educating parents, other adults, and teenagers about water safety. Parents must realize that young children who are left in or near water without adult supervision even for a short time can easily get into trouble, not just at the beach or next to a swimming pool, but in bathtubs and around toilets, buckets, washing machines, and other household articles where water can collect. Research on swimming pool drownings involving young children shows that the victims have usually been left unattended less than five minutes before the accident. Experts consider putting up a fence around a home swimming pool an essential precaution, and estimate that 50–90% of child drownings and near-drownings could be prevented if fences were widely adopted. The fence should be at least 5 ft (1.5 m) high and unclimbable, have a self-closing and self-locking gate, and completely surround the pool.

Pool owners—and, indeed, all other adults—should consider learning CPR. Everyone should follow the rules for safe swimming and boating. Those who have a medical condition that can cause a seizure or otherwise threaten safety in the water are advised always to swim with a partner. People also need to be aware that alcohol and drug use substantially increase the chances of an accident. The danger of alcohol and drug use around water requires special emphasis where teenagers are concerned. Teenagers can also benefit from CPR training and safe swimming and boating classes.

Drug metabolism/interactions

Definition

Drug metabolism is the process by which the body breaks down and converts medication into active chemical substances.

Precautions

Drugs can interact with other drugs, foods, and beverages. Interactions can lessen or magnify the desired therapeutic effect of a drug, or may cause unwanted or unexpected side effects. There are thousands of possible drug-to-drug and drug-to-food interactions, and many medications and supplements are contraindicated (not recommended) under certain conditions or in patients with specific diseases and disorders. This is why it is imperative that patients always keep their physician fully informed about all drugs and dietary supplements (including herbal remedies) they are taking.

Description

The primary site of drug metabolism is the liver, the organ that plays a major role in metabolism, digestion, **detoxification**, and elimination of substances from the body. Enzymes in the liver are responsible for chemically changing drug components into substances known as metabolites. Metabolites are then bound to other substances for excretion through the lungs, or bodily fluids such as saliva, sweat, breast milk, and urine, or through reabsorption by the intestines. The primary mode of excretion is through the kidneys.

The family of liver isoenzymes known as cytochrome P-450 are crucial to drug metabolism. These enzymes (labeled CYP1A2, CYP2C9, CYP2C19, CYP2D6, and CYP3A4) have a catabolic action on substances, breaking them down into metabolites. Consequently, they also act to lower the concentration of medication in the bloodstream.

Drug interactions can occur when one drug inhibits or induces a P-450 that acts on another drug. An example is nicotine, a drug contained in tobacco, and known to induce P-450s. Individuals with **liver disease** (e.g., **cirrhosis**) may also have insufficient levels of P-450 enzymes. As a result, the concentration of drugs metabolized by these enzymes (e.g., amprenavir and other **protease inhibitors**) remains high and can build up to toxic levels in the bloodstream. In addition, certain medications and foods, such as grapefruit juice, can inactivate or lessen the metabolic activity

WWW.BOOKBAZ.IR

of P-450s. Changing the drug dosage can alleviate the problem in some cases.

The metabolic rate can vary significantly from person to person, and drug dosages that work quickly and effectively in one individual may not work well for another. Factors such as genetics, environment, **nutrition**, and age also influence drug metabolism; infants and elderly patients may have a reduced capacity to metabolize certain drugs, and may require adjustments in dosage.

Causes and symptoms

Drugs that commonly interact with other medications include:

- Diuretics. Diuretics such as hydrochlorothiazide can reduce serum potassium and sodium electrolyte levels when taken with digoxin and lithium, respectively.
- Monoamine oxidase inhibitors (MAOIs). MAOI antidepressants can cause convulsions and other serious side effects when used with tricyclic antidepressants (e.g., Imipramine, Nortriptyline), selective serotonin reuptake inhibitors (SSRIs), or sympathomimetic drugs (e.g., amphetamines).
- Antibiotics. Antibiotics may reduce the efficiency of oral contraceptives.
- Metals. Medications containing metals, such as antacids with aluminum additives and iron supplements, can reduce the absorption of tetracyclines and fluoroquinolones.
- Drugs that inhibit liver enzyme function. Drugs that slow drug metabolism include ciprofloxacin, erythromycin, fluoxetine, nefazodone, paroxetine, and ritonavir. The therapeutic effect of other medications taken with these drugs may be amplified. Warfarin, a blood thinner, should be used with great caution in individuals taking these drugs.

Foods and beverages that may interact with drugs include:

- Grapefruit juice. Grapefruit juice inhibits the metabolism of many medications, including cyclosporine, felodipine, nifedipine, nitrendipine, nisoldipine, carbamazepine, triazolam, and midazolam.
- Foods and beverages with tyramines. Red wine, malted beers, smoked foods (e.g., fish and meats), dried fruits, and aged cheeses may contain tyramines, and can cause a severe and dangerous elevation in blood pressure when taken with MAOI inhibitors (a class of antidepressants).
- Dairy products. Milk, cream, and other dairy products containing calcium can prevention the absorption of antibiotics such as tetracycline, doxycycline, and ciprofloxacin when they are taken with the drug. In addition, whole milk with vitamin D can cause milk-alkali syndrome in patients taking aluminum hydroxide antacids.
- Caffeinated beverages. The caffeine contained in coffee and colas can influence drug metabolism.
- Alcohol. Alcohol is a central nervous system depressant, and should not be taken with other CNS depressants (e.g., antipsychotics, antihistamines). In addition, certain fermented beverages may contain tyramines.

This list is not all-inclusive and individuals should always let their doctor and pharmacist know when they are taking other medications, herbal remedies, or dietary supplements. Anyone who experiences a serious reaction to a drug that is not consistent with its product labeling should report the event to their doctor and/or the MedWatch adverse event reporting system of the United States Food and Drug Administration (FDA).

Alternatives

The growing use of herbal supplements has also increased the opportunity for adverse drug and herbal interactions. In 2000, the FDA issued a warning on the popular herb St. John's wort (*Hypericum perforatum*). The supplement was found to inhibit the effect of indinavir, a protease inhibitor used in the treatment of HIV. It may also affect the action of cyclosporine and other protease inhibitors (e.g., amprenavir, ritonavir). Further clinical studies are still necessary to determine the full metabolic effects of the herb.

Other herbs that may interact with allopathic medications include gingko bilboa, **ginseng**, and garlic, which may all heighten the blood thinning effect of the anticoagulant warfarin. Because herbs are regulated by the FDA as dietary supplements, they do not require the same extensive clinical trials and premarket testing as drugs do before they are cleared for sale in the United States. As such, there is still much to learn about the potential interactions and adverse effects associated with herbal supplements. Individuals who experience serious side effects from dietary supplements should report them to FDA's MedWatch program.

Diagnosis

Drug interactions can be difficult to detect. In some cases, adverse reactions may closely resemble the symptoms of the disease or condition the medication was prescribed to treat. Patients who take a

KEY TERMS

Catabolism—A process of metabolism that breaks down complex substances into simple ones.

Cirrhosis—Liver disease characterized by the widespread disruption of the normal liver structure and function.

CNS depressant—Anything that depresses, or slows, the sympathetic impulses of the central nervous system (i.e., respiratory rate, heart rate).

Drug interaction—A chemical or physiological reaction that can occur when two different drugs are taken together.

Enzymes—Organic substances (proteins) composed of amino acids that trigger and regulate chemical reactions in the body. There are over 700 identified human enzymes.

Liver—A solid organ located on the right in the upper abdomen. It plays a major role in metabolism, digestion, detoxification, and elimination of substances from the body.

Metabolism—The sum of all the physical and chemical processes occurring in the body to organize and maintain life.

Metabolites—Substances produced by metabolism or by a metabolic process.

Milk-alkali syndrome—Elevated blood calcium levels and alkalosis caused by excessive intake of milk and alkalis. Usually occurs in the treatment of peptic ulcer.

number of medications or self-treat with over-the-counter drugs and/or herbal remedies may not be able to determine which drug actually triggered the interaction. A 2001 study by University of Florida researchers found that less than half of the women participating disclosed their use of herbal therapies to their healthcare providers. In cases where a serious drug or herb interaction occurs, withholding this information can delay diagnosis and put the patient at increased risk.

Treatment

Treatment of a drug interaction is dependant on a number of factors, including the medication(s) or supplements used and the medical history of the patient. A dosage adjustment may reverse the effects of some interactions. Serious or life-threatening interactions will require more aggressive therapies.

Prevention

Patients with chronic health conditions, particularly those with liver disorders, should always inform their healthcare professional before taking any over-the-counter (OTC) medications or dietary supplements. Because of the risk for a drug-to-drug interaction, individuals should also let their doctor know if they are taking drugs prescribed by other physicians. Individuals should closely follow instructions for use and package directions on both prescription and over-the-counter drugs. Consulting with a pharmacist and/or physician may be beneficial if package directions are unclear to the patient.

As a rule, grapefruit juice should not be taken with medication unless recommended by a doctor. Patients taking MAOI inhibitors should always check food and beverage labels to ensure tyramines are not included, and should avoid all fermented drinks.

over-the-counter at the local drug store, or bought illegally on the street. Taken in combination with other drugs or with alcohol, even drugs normally considered safe can cause death or serious long term consequences. Children are particularly at risk for accidental overdose, accounting for over one million poisonings each year from drugs, alcohol, and other chemicals and toxic substances. People who suffer from depression and who have suicidal thoughts are also at high risk for drug overdose.

Causes and symptoms

Accidental drug overdose may be the result of misuse of prescription medicines or commonly used medications like **pain** relievers and cold remedies. Symptoms differ depending on the drug taken.

Acetaminophen is the generic name for the commonly used pain reliever Tylenol. Overdose of this drug causes liver damage with symptoms that include loss of appetite, tiredness, **nausea and vomiting**, paleness, and sweating. The next stage of symptoms indicates liver failure and includes abdominal pain and tenderness, swelling of the liver, and abnormal blood tests for liver enzymes. In the last stage of this **poisoning**, liver failure advances and the patient becomes jaundiced, with yellowing of the skin and whites of the eyes. They may also experience kidney failure, bleeding disorders, and **encephalopathy** (swelling of the brain).

Anticholinergic drugs (drugs that block the action of acetylcholine, a neurotransmitter) like atropine, scopolamine, belladonna, **antihistamines**, and antipsychotic agents cause the skin and moist tissues (like in the mouth and nose) to become dry and flushed. Dilated pupils, an inability to urinate, and mental disturbances are also symptoms. Severe toxicity can lead to seizures, abnormal heart rhythms, extremely high blood pressure, and **coma**.

Antidepressant drugs like amitriptyline, desipramine, and nortriptyline can cause irregular heart rate, **vomiting**, low blood pressure, confusion, and seizures. An overdose of antidepressants also causes symptoms similar to those seen with anticholinergic drug overdoses.

Cholinergic drugs (drugs that stimulate the parasympathetic nervous system) like carbamate and pilocarpine cause nausea, **diarrhea**, increased secretion of body fluids (sweat, tears, saliva, and urine), **fatigue**, and muscle weakness. Convulsions are possible. Death can occur due to **respiratory failure** and **heart failure**.

Cocaine and crack cocaine overdoses cause seizures, high blood pressure, increased heart rate, **paranoia**, and other changes in behavior. **Heart attack** or **stroke** are serious risks within three days after cocaine overdose.

Depressant drugs (tranquilizers, **antianxiety drugs**, sleeping pills) cause sleepiness, slowed or slurred speech, difficulty walking or standing, blurred vision, impaired ability to think, disorientation, and mood changes. Overdose symptoms can include slowed breathing, very low blood pressure, stupor, coma, **shock**, and death.

Digoxin, a drug used to regulate the heart, can cause irregular heart beats, nausea, confusion, loss of appetite, and blurred vision.

Narcotics or opiates are drugs like heroin, morphine, and codeine. Clonidine and diphenoxylate (Lomotil) are also in this category. Overdose with opiate drugs causes **sedation** (sleepiness), low blood pressure, slowed heart rate, and slowed breathing. Pinpoint pupils, where the black centers of the eyes become smaller than normal, are common in opiate overdose. However, if other drugs are taken at the same time as the opiates, they may counteract this effect on the pupils. A serious risk is that the patient will stop breathing.

Salicylates are found in **aspirin** and some creams or ointments used for muscle and joint pain (like Ben-Gay), and creams for **psoriasis**, a skin condition.

Initial symptoms are gastrointestinal irritation, **fever**, and vomiting, possibly with blood in the vomit. This overdose will cause **metabolic acidosis** and **respiratory alkalosis**, conditions where the body's acid/base balance is malfunctioning. Symptoms include rapid heart beat and fast breathing. Nervous system symptoms include confusion, **hallucinations**, tiredness, and ringing in the ears. An increased tendency to bleed is also common. Serious complications include acute renal failure, coma, and heart failure. Acute salicylate poisoning can lead to death.

Diagnosis

Diagnosis of a drug overdose may be based on the symptoms that develop, however, the drug may do extensive damage to the body before significant symptoms develop. If the patient is conscious, he or she may be able to tell what drugs were taken and in what amounts. The patient's recent medical and social history may also help in a diagnosis. For example, a list of medications that the patient takes, whether or not alcohol was consumed recently, even if the patient has eaten in the last few hours before the overdose, can be valuable in determining what was taken and how fast it will be absorbed into the system.

Different drugs have varying effects on the body's acid/base balance and on certain elements in the blood like potassium and **calcium**. Blood tests can be used to detect changes in body chemistry that may give clues to what drugs were taken. Blood can also be screened for various drugs in the system. Once the overdose drug is identified, blood tests can be used to monitor how fast the drug is being cleared out of the body. Urine tests can also be used to screen for some drugs and to detect changes in the body's chemistry. Blood and urine tests may show if there is damage to the liver or kidneys as a result of the overdose.

Treatment

Immediate care

If a drug overdose is discovered or suspected, and the person is unconscious, having convulsions, or is not breathing, call for emergency help immediately. If the person who took the drug is not having symptoms, do not wait to see if symptoms develop; call a poison control center immediately. Providing as much information as possible to the poison control center can help determine what the next course of action should be.

The poison control center, paramedics, and emergency room staff will want to know:

- What drug(s) were taken? (Try to locate the drug's container.)
- How much of the drug was taken?
- When was the drug taken?
- Was the drug taken with alcohol or any other drugs or chemicals?
- What is the age of the patient?
- What symptoms are the patient experiencing?
- Is the patient conscious?
- Is the patient breathing?

The poison control center may recommend trying to get the patient to vomit. A liquid called **ipecac** syrup, which is used to induce vomiting, is available from pharmacies without a prescription. Pediatricians may recommend that families keep ipecac syrup on hand in households with children. This medication should be used only on the advice of a medical professional. Vomiting should not be induced if the patient is unconscious.

Emergency care

Emergency medical treatment may include:

- Assessment of the patient's airway and breathing to making sure that the trachea, the passage to the lungs, is not blocked. If needed, a tube may be inserted through the mouth and into the trachea to help the patient breath. This procedure is called intubation.
- Assessment of the patient's heart rate, blood pressure, body temperature, and other physical signs that might indicate the effects of the drug.
- Blood and urine samples may be collected to test for the presence of the suspected overdose drug, and any other drugs or alcohol that might be present.
- Elimination of the drug that has not yet been absorbed is attempted. Vomiting may be induced using ipecac syrup or other drugs that cause vomiting. Ipecac syrup should not be given to patients who overdosed with tricyclic antidepressants, theophylline, or any drug that causes a significant change in mental status. If a patient vomits while unconscious, there is a serious risk of choking.
- Gastric lavage, or washing out the stomach, may be attempted. For this procedure a tube flexible tube is inserted through the nose, down the throat, and into the stomach. The contents of the stomach are then suctioned out through the tube. A solution of saline (salt water) is injected into the tube to rinse out the stomach. This solution is then suctioned out. This is

WWW.BOOKBAZ.IR

KEY TERMS

Gastric lavage—Also called a stomach pump. For this procedure, a flexible tube is inserted through the nose, down the throat, and into the stomach and the contents of the stomach are suctioned out. The inside of the stomach is rinsed with a saline (salt water) solution.

Intubation—A procedure where a tube is inserted through the mouth and into the trachea keep the airway open and to help the patient breathe.

the process used when someone has his/her stomach pumped.

- Activated charcoal is sometimes given to absorb the drug.
- Medication to stimulate urination or defecation may be given to try to flush the excess drug out of the body faster.
- Intravenous (IV) fluids may be given. An intravenous line, a needle inserted into a vein, may be put into the arm or back of the hand. Fluids, either sterile saline (salt water solution) or dextrose (sugar water solution), can be administered through this line. Increasing fluids can help to flush the drug out of the system and to reestablish balance of fluids and minerals in the body. The pH (acid/base balance) of the body may need to be corrected by administering electrolytes like sodium, potassium, and bicarbonate through this IV line. If drugs need to be administered quickly, they can also be injected directly into the IV line.
- Hemodialysis is a procedure where blood is circulated out of the body, pumped through a dialysis machine, then reintroduced back into the body. This process can be used to filter some drugs out of the blood. It may also be used temporarily or long term if the kidneys are damaged due to the overdose.
- Antidotes are available for some drug overdoses. An antidote is another drug that counteracts or blocks the overdose drug. For example, acetaminophen overdose can be treated with an oral medication, N-acetylcysteine (Mucomyst), if the level of acetaminophen found in the blood is extremely high. Naloxone is an anti-narcotic drug that is given to counteract narcotic poisoning. Nalmefen or methadone may also be used.
- Psychiatric evaluation may be recommended if the drug overdose was taken deliberately.

Prognosis

While many victims of drug overdose recover without long term effects, there can be serious consequences. Some drug overdoses cause the failure of major organs like the kidneys or liver, or failure of whole systems like the respiratory or circulatory systems. Patients who survive drug overdose may need **kidney dialysis**, kidney or liver transplant, or ongoing care as a result of heart failure, stroke, or coma. Death can occur in almost any drug overdose situation, particularly if treatment is not started immediately.

Prevention

To protect children from accidental drug overdose, all medications should be stored in containers with child resistant caps. All drugs should be out of sight and out of reach of children, preferably in a locked cabinet. Prescription medications should be used according to directions and only by the person whose name is on the label. Threats of **suicide** need to be taken seriously and appropriate help sought for people with depression or other mental illness that may lead to suicide.

Drug therapy monitoring

Definition

Drug therapy monitoring, also known as Therapeutic Drug Monitoring (TDM), is a means of monitoring drug levels in the blood.

Purpose

TDM is employed to measure blood drug levels so that the most effective dosage can be determined, with toxicity prevented. TDM is also utilized to identify

Therapeutic Drug Monitoring: Therapeutic and toxic ranges

Drug name	Use	Therapeutic level*	Toxic level
Acetaminophen	Analgesic, antipyretic	Depends on use	>250 mcg/mL
Amikacin	Antibiotic	12–25 mcg/mL**	>25
Aminophylline	Bronchodilator	10–20 mg/mL	>20
Amitriptyline	Antidepressant	120–150 ng/mL	>500
Carbamazepine	Anticonvulsant	5–12 mg/mL	>12
Chloramphenicol	Antibiotic	10–20 mcg/mL	>25
Digoxin	Cardiotonic	0.8–2.0 ng/mL	>2.4
Gentamicin	Antibiotic	5–10 mcg/mL	>12
Lidocaine	Antiarrhythmic	1.5–5.0 mcg/mL	>5
Lithium	Antimanic	0.8–1.2 mEq/L	>2.0
Nortriptyline	Antidepressant	50–150 ng/mL	>500
Phenobarbital	Anticonvulsant	10–30 mcg/mL	>40
Phenytoin	Anticonvulsant	10–20 mcg/mL	>30
Procainamide	Antiarrhythmic	4–10 mcg/mL	>16
Propranolol	Antiarrhythmic	50–100 ng/mL	>150
Quinidine	Antiarrhythmic	2–5 mcg/mL	>10
Salicylate	Analgesic	100–250 mcg/mL	>300
Theophylline	Bronchodilator	10–20 mg/mL	>20
Tobramycin	Antibiotic	5–10 mcg/mL**	>12
Valproic acid	Anticonvulsant	50–100 mcg/mL	>100

*Values are laboratory-specific.
**Concentration obtained 30 minutes after the end of a 30-minute infusion.

SOURCE: National Institutes of Health, U.S. National Library of Medicine.

(Table by PreMediaGlobal. © Cengage Learning®.)

noncompliant patients (those patients who, for whatever reason, either cannot or will not comply with drug dosages as prescribed by the physician).

Precautions

Because so many different factors influence blood drug levels, the following points should be taken into consideration during TDM: the age and weight of the patient; the route of administration of the drug; the drug's absorption rate, excretion rate, delivery rate, and dosage; other medications the patient is taking; other diseases the patient has; the patient's compliance regarding the drug treatment regimen; and the laboratory methods used to test for the drug.

Description

TDM is a practical tool that can help the physician provide effective and safe drug therapy in patients who need medication. Monitoring can be used to confirm a blood drug concentration level that is above or below the therapeutic range, or if the desired therapeutic effect of the drug is not as expected. If this is the case, and dosages beyond normal then have to be prescribed, TDM can minimize the time that elapses.

TDM is important for patients who have other diseases that can affect drug levels, or who take other medicines that may affect drug levels by interacting with the drug being tested. As an example, without drug monitoring, the physician cannot be sure if a patient's lack of response to an antibiotic reflects bacterial resistance, or is the result of failure to reach the proper therapeutic range of antibiotic concentration in the blood. In cases of life-threatening infections, timing of effective antibiotic therapy is critical to success. It is equally crucial to avoid toxicity in a seriously ill patient. Therefore, if toxic symptoms appear with standard dosages, TDM can be used to determine changes in dosing.

Drawn blood, used for TDM, demonstrates a drug action in the body at any specific time, whereas drug levels examined from urine samples reflect the presence of a drug over many days (depending on the rate of excretion). Therefore, blood testing is the procedure of choice when definite data are required. However, for adequate absorption and therapeutic levels to be accurate, it is important to allow for sufficient time to pass between the administration of the medication and the collection of the blood sample.

Blood specimens for drug monitoring can be taken at two different times: during the drug's highest therapeutic concentration ("peak" level), or its lowest ("trough" level). Occasionally called residual levels, trough levels show sufficient therapeutic levels; whereas peak levels show **poisoning** (toxicity). Peak and trough levels should fall within the therapeutic range.

Preparation

In preparing for this test, the following guidelines should be observed:

- Depending on the drug to be tested, the physician should decide if the patient is to be fasting (nothing to eat or drink for a specified period of hours) before the test.
- For patients suspected of symptoms of drug toxicity, the best time to draw the blood specimen is when the symptoms are occurring.
- If there is a question as to whether an adequate dose of the drug is being achieved, it is best to obtain trough (lowest therapeutic concentration) levels.

WWW.BOOKBAZ.IR

- Peak (highest concentration) levels are usually obtained one to two hours after oral intake, approximately one hour after intramuscular (IM) administration (a shot in the muscle), and approximately 30 minutes after intravenous (IV) administration. Residual, or trough, levels are usually obtained within 15 minutes of the next scheduled dose.

Risks

Risks for this test are minimal, but may include slight bleeding from the blood-drawing site, **fainting** or feeling lightheaded after blood is drawn, or accumulation of blood under the puncture site (hematoma).

Drugs used in labor

Definition

These drugs are used to induce (start) or continue labor.

Purpose

Oxytocin is a drug used to make the uterus (womb) contract. Physicians use it to deliberately start labor. Because there are some risks with using oxytocin, this should be done only when there are good medical reasons. Any woman who is being given oxytocin should make sure she has discussed the benefits and risks with her physician.

Oxytocin also may be used to control bleeding after delivery or to help make the milk flow in women who are **breastfeeding** their babies.

Description

Oxytocin is a hormone and is available only with a physician's prescription. When used to start or continue labor, it is slowly injected into a vein. A nasal spray form is used to increase milk flow in breastfeeding. Some commonly used brand names are Pitocin and Syntocinon.

KEY TERMS

Cesarean section—The delivery of a baby through a surgical procedure.

Fetus—A developing baby inside the womb.

Hormone—A substance that is produced in one part of the body, then travels through the bloodstream to another part of the body where it has its effect.

Recommended dosage

Doses may be different for different patients. Follow the orders of the physician who prescribed the drug.

For increasing milk production

One spray into one or both nostrils, 2–3 minutes before nursing or using a breast pump.

For starting or continuing labor

The physician in charge will determine the appropriate dose.

Precautions

Oxytocin does not help increase or continue labor in all patients. When it does not help, the physician may deliver the baby by **cesarean section**.

In women who are especially sensitive to oxytocin, the drug may cause contractions to become too strong. This could tear the uterus or deprive the fetus of blood and oxygen during labor.

Oxytocin does not help improve milk flow in all women who are breastfeeding. Check with a physician if the drug does not seem to be working.

Women with **heart disease**, high blood pressure, or **kidney disease** should let their physicians know about these conditions before taking oxytocin. Also, anyone who has had an unusual reaction to oxytocin in the past should inform their physician.

Side effects

Oxytocin has caused irregular heartbeat and increased bleeding in some women after delivery. It may also cause **jaundice** (yellowing of the eyes and skin) in newborns.

Other side effects are rare, but may include nausea, **vomiting**, confusion, **dizziness**, convulsions, breathing problems, **headache**, **hives**, skin rash, **itching**, pelvic or abdominal **pain**, and weakness. The nasal spray form may cause watery eyes or irritation of the nose.

Interactions

Anyone who takes oxytocin should let the physician know all other medicines she is taking.

Nancy Ross-Flanigan

KEY TERMS

Salivary duct—Tube through which saliva is carried from the salivary gland to the mouth.

Salivary gland—Gland in which saliva forms.

Sialogogue—A medication given to increase the flow of saliva.

Xerostomia—The medical term for dry mouth.

Dry mouth

Definition

Dry mouth, known medically as xerostomia, is the abnormal reduction of saliva due to medication, disease, or medical therapy.

Description

Dry mouth due to the lack of saliva can be a serious medical problem. Decreased salivation can make swallowing difficult, can decrease taste sensation, and can promote **tooth decay**.

Causes and symptoms

Dry mouth, resulting from thickened or reduced saliva flow, can be caused by a number of factors: medications, both prescription and over-the-counter; such systemic diseases as anemia, HIV infection, or diabetes, manifestations of Sjögren's syndrome (as **rheumatoid arthritis**, lupus, chronic hardening and thickening of the skin, or chronic and progressive inflammation of skeletal muscles); infections of the salivary glands; blockage of the salivary ducts caused by stones or tumors forming in the ducts through which the saliva passes; **dehydration**; such medical therapies as local surgery or radiation; secretion reduction normally involved in the **aging** process; and emotional **stress**.

Diagnosis

The diagnosis of dry mouth is not difficult. The patient will state that his or her saliva is very thick or nonexistent. Finding the cause of dry mouth may be more difficult and require some laboratory testing. Salivary gland biopsy for stones or tumors should be performed if indicated.

Treatment

The treatment of dry mouth involves the management of the condition causing it. If dry mouth is caused by medication, the medication should be changed. If dry mouth is caused by blockage of the salivary ducts, the cause of the blockage should be investigated. When systemic diseases, such as diabetes and anemia, are brought under control dry mouth problems may decrease.

The use of caffeine-containing beverages, alcoholic beverages, and mouthwashes containing alcohol should be minimized. The drinking of water and fruit juices will decrease dry mouth problems. Chewing gum and lemon drops can be used to stimulate saliva flow. Bitters also can initiate salivary flow as long as the salivary glands and ducts are functional. Commercial saliva substitutes are available without prescription and can be used as frequently as needed. Use of a humidifier in the bedroom reduces nighttime oral dryness.

Dry mouth caused by the aging process or **radiation therapy** for cancer can be treated by such oral medications as pilocarpine (Salagen). Drugs that are given to increase the flow of saliva are known as sialogogues.

Prognosis

The prognosis for patients with xerostomia due to medication problems is good, if the offending agent can be changed. Dry mouth due to systemic problems may be eliminated or improved once the disease causing the dry mouth is under control. Persistent xerostomia can be managed well with saliva substitutes.

WWW.BOOKBAZ.IR

Prevention

A patient needs to ask his or her health care provider if any medication to be prescribed will cause dry mouth. Patients with persistent xerostomia need to practice good **oral hygiene** and visit a dentist on a regular basis; the lack of adequate saliva can cause severe dental decay. The salivary glands are very sensitive to radiation, so any patient scheduled for radiation therapy of the head and neck needs to discuss with the radiation therapist ways to minimize exposure of the salivary glands to radiation.

Dukan diet

Definition

The Dukan diet is a high-protein, low-carbohydrate diet devised and promoted by a French physician, Pierre Dukan (1941–). First published in France in 2000, the Dukan diet is roughly similar to the Atkins diet. It was not well known in the English-speaking world until Kate Middleton, the new duchess of Cambridge, provided the diet with considerable publicity in 2010. The British press reported that she had used it to drop two dress sizes prior to her 2011 wedding to Prince William. It was precisely this association with celebrity that led the British Dietetic Association to list the Dukan diet for each year between 2010 and 2014 as among the top five **diets** to avoid.

Dukan was dropped from the French register of licensed physicians in January 2014 for promoting his diet as a profit-making business. Dukan, who was a general practitioner rather than an expert in **nutrition**, made himself notorious in 2012 by suggesting that all French high school graduates preparing for the *baccalauréat*, a stiff academic examination required for entrance to all French universities, should be given one test as part of "le bac" that they could pass simply by keeping their weight within the proper limits for their age and sex.

Description

The Dukan diet is a protein-based diet that emphasizes strict adherence to a list of permitted foods rather than calorie-counting or portion size. It consists of four phases, the first two focused on weight loss and the second two on weight stabilization and maintenance. Dieters can eat as much as they want during all four phases of the diet, provided that they stick to the list of foods allowed in each phase. Another distinctive feature of the Dukan diet is oat bran; dieters are required to eat between 1.5 and 3 tablespoons of oat bran per day, depending on the phase of the diet. Alcohol is not permitted until the dieter reaches the third phase of the diet.

The four phases of the Dukan Diet are as follows:

- Attack: Lasting from 2 days for people who need to lose only 10 lb (4.5 kg) to 7 to 10 days for those with 40 lb (18 kg) or more to lose, the Attack phase is the pure protein phase of the Dukan diet. Dieters are given a list of 68 permitted protein foods that they can eat in unlimited quantities: lean beef, veal, pork, and venison; organ meat (i.e., liver, tongue); fish;

Phases of the Dukan Diet

Phase	Time period	Food	Weight loss
Attack	1–10 days	Unlimited protein (animal, nonfat dairy, vegetarian), 1.5 tbsp oat bran/day, at least 6 cups water/day. Exercise daily for 20 minutes.	2-8 pounds
Cruise	Several months (averaging 3 days per pound)	In addition to following the "attack" phase, add unlimited non-starchy vegetables every other day and an additional 0.5 tbsp oat bran/day. Exercise daily for 30 minutes.	Approximately 2 pounds/week
Consolidation	5 days for every pound lost	Add 1 piece fruit, 2 slices whole grain bread, 1 serving hard cheese, unlimited vegetables every day. 1-2 servings of starchy foods and 1-2 "cheat" meals per week. On Thursdays, eat only "attack" phase foods. Exercise daily for 25 minutes.	
Stabilization	Ongoing after weight is lost	Unlimited food from all food groups, 3 tbsp oat bran/day, plus follow the all-protein plan from the "attack" phase on Thursdays. Exercise daily for 20 minutes.	

(Illustration by Electronic Illustrators Group. © Cengage Learning®.)

shellfish; poultry; low-fat ham, turkey, and chicken; eggs; tofu; nonfat dairy products; and 6–8 glasses of water daily to flush out ketones (breakdown products of fat metabolism) from the body. The dieter must also consume 1.5 tablespoons of oat bran per day and start exercising. The Dukan diet recommends 25 minutes of brisk walking per day as exercise in this phase.

- Cruise: The Cruise phase is intended to promote slow but steady weight loss, about 1 lb (0.5 kg) every 3 days. It lasts until dieters reach their goal weight. In addition to the 68 permitted protein foods, dieters are now allowed 32 non-starchy vegetables such as lettuce, spinach, cucumbers, mushrooms, and zucchini. Dieters are instructed to alternate pure protein (PP) days, using only the foods allowed in the Attack phase, with protein and vegetable (PV) days. Dieters have the option of alternating 2 PP with 2 PV or 3 PP with 3 PV days depending on their lifestyle. The oat bran intake is raised to 2 tablespoons per day and exercise to 30 minutes of brisk walking.
- Consolidation: The third phase of the Dukan diet is intended to prevent regaining the lost weight. Dieters are instructed to remain in the Consolidation phase five days for every pound lost, which means almost two months for dieters who needed to lose 10 lb (4.5 kg) and the better part of a year for someone who needed to lose 40 lb (18 kg). Dieters are still restricted to the 100 basic foods that can be eaten in unlimited quantities but can combine them in any way they prefer. In addition, limited quantities of fruit, bread, cheese, pasta, and fattier meats such as lamb or pork are allowed on a weekly basis. Dieters are allowed two so-called celebration meals each week, although the meals may not be eaten back to back and binging is not allowed. A celebration meal includes an appetizer, main dish, dessert, and glass of wine. The daily oat bran intake remains at 2 tablespoons.
- Stabilization: The Stabilization phase is intended to continue for the rest of the dieters' life. They may eat whatever they prefer six days of the week provided that the guidelines learned during the Consolidation phase are not forgotten. On the seventh day, however, they must return to the pure protein diet of the Attack phase. The daily oat bran intake is now 3 tablespoons, and dieters are expected to continue the daily brisk walk.

Purpose

The purpose of the Dukan diet is initial rapid weight loss followed by a phase of slower weight loss and then permanent weight stabilization. Dukan uses the expression *True Weight* to refer to the weight that dieters can reach relatively easily. The True Weight is

WWW.BOOKBAZ.IR

the weight that dieters are most likely to be able to maintain long term. The Dukan website allows dieters to calculate their True Weight online; the formula takes into account weight history and other specifics regarding gender, age, highest weight, lowest weight, desired weight, average weight, heredity, bone structure, and number of pregnancies for women.

Preparation

As with any weight reduction diet, individuals considering this diet should consult a physician beforehand to make sure they do not have any condition that would make dieting unwise or harmful to health. With that provision, the Dukan diet does not require any special preparation other than learning the basic information about the rules of the diet from the official website or one of the Dukan diet books and purchasing the appropriate foods for the Attack phase. Some observers have noted that these preparations are expensive, with high-protein foods such as meat and nonfat dairy being among the pricier selections in any grocery store. Dieters who need to eat large portions of these foods in order to feel full may find themselves with high grocery bills. The 2011 U.S. edition of the Dukan diet book cost $26 in hardcover, $11 in the Amazon Kindle e-book form. In addition, the coaching service recommended for the first three phases of the diet on the Dukan website cost $29.95 per month, with some users reporting disappointment with the service. The Dukan website also offered a range of products for dieters, including the recommended oat bran, 4.4 lb (2 kg) for $19. The diet foods include kosher versions of Dukan products as well as goji berries (8 oz for $17) and freeze-dried butternut squash (1.1 oz for $6.69).

Aftercare

Aftercare for the Dukan diet is the Stabilization phase and optional personalized coaching.

Risks

As of 2014, the Dukan diet had not been evaluated in any U.S. clinical trials. In addition to the lack of clinical evaluation, the Academy of Nutrition and Dietetics did not recommend the Dukan diet, finding it deficient in carbohydrate intake, unsuitable for vegetarians, and placing dieters at risk of kidney problems or **gout** during the highly restrictive Attack and Cruise phases. Other side effects of the diet during the first two phases include **bad breath**, **dry mouth**, **constipation**, and **fatigue**. The Academy also noted that most of the weight loss during the Attack phase was likely to be water rather than fat.

KEY TERMS

Ketoacidosis—An abnormal metabolic condition in which the body fails to regulate the production of ketone bodies, leading to a drop in the pH of the blood.

Ketone bodies—Water-soluble molecules produced by the liver from fatty acids during periods of starvation or calorie-reduction dieting coupled with restricted intake of carbohydrates.

Seitan—The Japanese name for a meat substitute made of wheat gluten. Some vegans prefer seitan to tofu because its texture is stringier and resembles that of meat.

True weight—Dukan's term for the weight that a dieter can maintain long term without struggling or damage to health. It takes the dieter's age, sex, family background, pregnancy history, and similar factors into account. For many people, the true weight may well be higher than what they would consider their ideal weight.

Vegan—A strict vegetarian diet, which does not include eggs, meat, dairy products, and all other dietary choices derived from animals.

According to an analysis published by *U.S. News and World Report*, the Dukan diet has some other nutritional deficiencies or drawbacks:

- The Attack phase and the pure protein days of the later phases provide much higher levels of sodium than are recommended.
- The diet is deficient in fiber, potassium, and vitamin D in all four phases. Dieters who want to follow the Dukan diet should consider a multivitamin supplement.
- The Attack and Cruise phases do not meet the USDA recommendations for carbohydrates.
- Vegans would find the diet especially difficult because the only foods they could eat during the Attack phase are tofu and seitan. Vegetarians who allow themselves dairy products can have milk and yogurt as well.

Although such cases are rare, some people using the Dukan Diet may develop ketoacidosis, an

abnormal metabolic condition in which the metabolism of fatty acids leads to the presence of large numbers of ketone bodies in the blood without sufficient insulin to slow their production. The excess ketone bodies can acidify the blood, leading to severe **nausea and vomiting**. In 2014, a team of physicians in South Carolina reported the case of a woman who required emergency treatment for severe **vomiting** after only two days on the Dukan diet. The authors recommend that persons starting the Dukan diet (or any similar high-protein, low-carbohydrate diet) tell their physician beforehand.

Rebecca J. Frey, Ph.D.

Duodenal atresia *see* **Duodenal obstruction**

Duodenal obstruction

Definition

Duodenal obstruction is a failure of food to pass out of the stomach either from a complete or partial obstruction.

Description

The duodenum is the first part of the intestine, into which the stomach, the gall bladder, and the pancreas empty their contents. The pylorus connects the duodenum with the stomach and contains the valve that regulates stomach emptying. Obstruction usually occurs right at this outlet, so that the gall bladder and pancreas are unable to drain their secretions without hindrance.

Causes and symptoms

Obstruction of the duodenum occurs in adults and infants, each for a different set of reasons. In adults, the usual cause is a peptic ulcer of such antiquity that repeated cycles of injury and scarring have narrowed the passageway. Medical treatment of **ulcers** has progressed to the point where such obstinate ulcer disease is rarely seen any more. In infants, the conditions are congenital—either the channel is underdeveloped or the pylorus is overdeveloped. The first type is called duodenal hypoplasia and the second is termed hypertrophic **pyloric stenosis**. In rare cases, the channel may be missing altogether, a condition called duodenal atresia. To say that these anomalies are congenital is not to say their cause is understood. As with most **birth defects**, the specific cause is not known.

Food that cannot exit the stomach in the forward direction will return whence it came. **Vomiting** is the constant symptom of duodenal obstruction. It may be preceded by **indigestion** and nausea as the stomach attempts to squeeze its contents through an ever narrowing outlet.

Hypertrophic pyloric stenosis appears soon after birth. The infant will vomit feedings, lose weight, and be restless and irritable.

Diagnosis

X rays taken with contrast material in the stomach readily demonstrate the site of the blockage and often the ulcer that caused it. Gastroscopy is another way to evaluate the problem. In infants, x rays may not be necessary to detect pyloric stenosis. It is often possible to feel the enlarged pylorus, like an olive, deep under

WWW.BOOKBAZ.IR

KEY TERMS

Atresia—Failure to develop; complete absence.

Contrast agent—A substance that produces shadows on an x ray so that hollow structures can be more easily seen.

Gastroscopy—Looking into the stomach with a flexible viewing instrument called a gastroscope.

Hypoplasia—Incomplete development.

Peptic ulcer—A wound in the lower stomach and duodenum caused by stomach acid and a newly discovered germ called *Helicobacter pylori*.

the ribs and see the stomach rippling as it labors to force food through.

Treatment

Bowel obstruction requires a surgeon, sometimes immediately. Newer surgical techniques constantly improve the outcome, but obstruction is a mechanical problem that needs a mechanical solution. Most adults who come to surgery for obstruction have suffered for years from peptic ulcer disease. They will usually benefit from ulcer surgery at the same time their obstruction is relieved. The surgeon will select a procedure that combines relief of obstruction with remedy for ulcer disease. There are many choices. In fact, even without obstruction, functional considerations require ulcer surgery to include enhancement of stomach emptying.

To treat an infant with hypertrophic pyloric stenosis, some surgeons have had success with forceful balloon dilation of the pylorus done through a gastroscope, but the standard procedure is to cut across the overdeveloped circular muscle that is constricting the stomach outlet. There are reports of infant hypertrophic pyloric stenosis remitting without surgery following a very careful feeding schedule, but mortality is unacceptably high.

Prognosis

A functioning and unrestricted intestine is a prerequisite for living independent of the most advanced and continuous medical care available. Achieving this desirable goal is the rule with surgery for duodenal obstructions of all types. The bowel is so malleable that there is a rearrangement to suit every occasion. The variety of possible configurations is limited only by the surgeon's imagination.

Prevention

Prompt and effective treatment of peptic ulcers will prevent chronic scarring and narrowing. Drugs developed over the past few decades have all but eliminated the need for ulcer surgery.

Dysentery

Definition

Dysentery is a general term for a group of gastrointestinal disorders characterized by inflammation of the intestines, particularly the colon. Characteristic features include abdominal **pain** and cramps, straining at stool (tenesmus), and frequent passage of watery **diarrhea** or stools containing blood and mucus. The English word dysentery comes from two Greek words meaning "ill" or "bad" and "intestine."

It should be noted that some doctors use the word "dysentery" to refer only to the first two major types of dysentery, while others use the term in a broader sense. For example, some doctors speak of **schistosomiasis**, a disease caused by a parasitic worm, as bilharzial dysentery, while others refer to acute diarrhea caused by viruses as viral dysentery.

Description

Dysentery is a common but potentially serious disorder of the digestive tract that occurs throughout the world. It can be caused by a number of infectious agents ranging from viruses and bacteria to protozoa

and parasitic worms; it may also result from chemical irritation of the intestines. Dysentery is one of the oldest known gastrointestinal disorders, having been described as early as the Peloponnesian War in the fifth century B.C. Epidemics of dysentery were frequent occurrences aboard sailing vessels as well as in army camps, walled cities, and other places in the ancient world where large groups of human beings lived together in close quarters with poor sanitation. As late as the eighteenth and nineteenth centuries, sailors and soldiers were more likely to die from the "bloody flux" than from injuries received in battle. It was not until 1897 that a bacillus (rod-shaped bacterium) was identified as the cause of one major type of dysentery.

Dysentery in the modern world is most likely to affect people in the less developed countries and travelers who visit these areas. According to the Centers for Disease Control and Prevention (CDC), most cases of dysentery in the United States occur in immigrants from the developing countries and in persons who live in inner-city housing with poor sanitation. Other groups of people at increased risk of dysentery are military personnel stationed in developing countries, frequent travelers, children in day care centers, people in nursing homes, and men who have sex with other men.

Causes and symptoms

Causes

The most common types of dysentery and their causal agents are as follows:

- Bacillary dysentery. Bacillary dysentery, which is also known as **shigellosis**, is caused by four species of the genus *Shigella*: *S. dysenteriae*, the most virulent species and the one most likely to cause epidemics; *S. sonnei*, the mildest species and the most common form of *Shigella* found in the United States; *S. boydii*; and *S. flexneri*. *S. flexneri* is the species that causes Reiter's syndrome, a type of arthritis that develops as a late complication of shigellosis. About 15,000 cases of shigellosis are reported to the CDC each year for the United States; however, the CDC maintains that the true number of annual cases may be as high as 450,000, since the disease is vastly underreported. About 85% of cases in the United States are caused by *S. sonnei*. The *Shigella* organisms cause the diarrhea and pain associated with dysentery by invading the tissues that line the colon and secreting an enterotoxin, or harmful protein that attacks the intestinal lining.
- Amebic dysentery. Amebic dysentery, which is also called intestinal amebiasis and amebic colitis, is caused by a protozoon, *Entamoeba histolytica*. *E. histolytica*, whose scientific name means "tissue-dissolving," is second only to the organism that causes malaria as a protozoal cause of death. *E. histolytica* usually enters the body during the cyst stage of its life cycle. The cysts may be found in food or water contaminated by human feces. Once in the digestive tract, the cysts break down, releasing an active form of the organism called a trophozoite. The trophozoites invade the tissues lining the intestine, where they are usually excreted in the patient's feces. They sometimes penetrate the lining itself, however, and enter the bloodstream. If that happens, the trophozoites may be carried to the liver, lung, or other organs. Involvement of the liver or other organs is sometimes called metastatic amebiasis.
- Balantidiasis, giardiasis, and cryptosporidiosis. These three intestinal infections are all caused by protozoa, *Balantidium coli*, *Giardia lamblia*, and *Cryptosporidium parvum* respectively. Although most people infected with these protozoa do not become severely ill, the disease agents may cause dysentery in children or immunocompromised individuals. There are about 3,500 cases of cryptosporidiosis reported to the CDC each year in the United States, and about 22,000 cases of giardiasis.
- Viral dysentery. Viral dysentery, which is sometimes called traveler's diarrhea or viral gastroenteritis, is caused by several families of viruses, including rotaviruses, caliciviruses, astroviruses, noroviruses, and adenoviruses. There are about 3.5 million cases of viral dysentery in infants in the United States each year, and about 23 million cases each year in adults. The CDC estimates that viruses are responsible for 9.2 million cases of dysentery related to food poisoning in the United States each year. Whereas most cases of viral dysentery in infants are caused by rotaviruses, caliciviruses are the most common disease agents in adults. Noroviruses were responsible for about half of the outbreaks of dysentery on cruise ships reported to the CDC in 2002.
- Dysentery caused by parasitic worms. Both whipworm (trichuriasis) and flatworm or fluke (schistosomiasis) infestations may produce the violent diarrhea and abdominal cramps associated with dysentery. Schistosomiasis is the second most widespread tropical disease after malaria. Although the disease is rare in the United States, travelers to countries where it is endemic may contract it. The World Health Organization (WHO) estimates that about 200 million people around the world carry the parasite in their bodies, with 20 million having severe disease.

WWW.BOOKBAZ.IR

Symptoms

In addition to the characteristic bloody and/or watery diarrhea and abdominal cramps of dysentery, the various types have somewhat different symptom profiles:

- Bacillary dysentery. The symptoms of shigellosis may range from the classical bloody diarrhea and tenesmus characteristic of dysentery to the passage of nonbloody diarrhea that resembles the loose stools caused by other intestinal disorders. The high fever associated with shigellosis begins 1–3 days after exposure to the organism. The patient may also have pain in the rectum as well as abdominal cramping. The acute symptoms last 3–7 days, occasionally for as long as a month. Bacillary dysentery may lead to two potentially fatal complications outside the digestive tract: bacteremia (bacteria in the bloodstream), which is most likely to occur in malnourished children; and hemolytic uremic syndrome, a type of kidney failure that has a mortality rate above 50%.
- Amebic dysentery. Amebic dysentery often has a slow and gradual onset; most patients with amebiasis visit the doctor after several weeks of diarrhea and bloody stools. Fever is unusual with amebiasis unless the patient has developed a liver abscess as a complication of the infection. The most serious complication of amebic dysentery is fulminant or necrotizing colitis, which is a severe inflammation of the colon characterized by dehydration, severe abdominal pain, and the risk of perforation (rupture) of the colon.
- Dysentery caused by other protozoa. Dysentery associated with giardiasis begins about 1–3 weeks after infection with the organism. It is characterized by bloating and foul-smelling flatus, nausea and vomiting, headaches, and low-grade fever. These acute symptoms usually last 3–4 days. The symptoms of cryptosporidiosis are mild in most patients but are typically severe in patients with AIDS. Diarrhea usually starts between seven and 10 days after exposure to the organism and may be copious. The patient may have pain in the upper right abdomen, nausea, and vomiting, but fever is unusual.
- Viral dysentery. Viral dysentery has a relatively rapid onset; symptoms may begin within hours of infection. The patient may be severely dehydrated from the diarrhea but usually has only a low-grade fever. The diarrhea itself may be preceded by 1–3 days of nausea and vomiting. The patient's abdomen may be slightly tender but is not usually severely painful.
- Dysentery caused by parasitic worms. Patients with intestinal schistosomiasis typically have a gradual onset of symptoms. In addition to bloody diarrhea and abdominal pain, these patients usually have fatigue. An examination of the patient's colon will usually reveal areas of ulcerated tissue, which is the source of the bloody diarrhea.

Diagnosis

Patient history and physical examination

The **physical examination** in the primary care doctor's office will not usually allow the doctor to determine the specific parasite or other disease agent that is causing the bloody diarrhea and other symptoms of dysentery, although the presence or absence of **fever** may help to narrow the diagnostic possibilities. The patient's age and history are usually better sources of information. The doctor may ask about such matters as the household water supply and food preparation habits, recent contact with or employment in a nursing home or day care center, recent visits to tropical countries, and similar questions. The doctor will also need to know when the patient first noticed the symptoms.

The doctor will also evaluate the patient for signs of **dehydration** resulting from the loss of fluid through the intestines. **Fatigue**, drowsiness, dryness of the mucous membranes lining the mouth, low blood pressure, loss of normal skin tone, and rapid heartbeat (above 100 beats per minute) may indicate that the patient is dehydrated.

Laboratory tests

The most common laboratory test to determine the cause of dysentery is a stool sample. The patient should be asked to avoid using over-the-counter **antacids** or antidiarrheal medications until the sample has been collected, as these preparations can interfere with the test results. The organisms that cause **cryptosporidiosis**, bacillary dysentery, amebic dysentery, and **giardiasis** can be seen under the microscope, as can the eggs produced by parasitic worms. In some cases repeated stool samples, a sample of mucus from the intestinal lining obtained through a proctoscope, or a tissue sample from the patient's colon may be necessary to confirm the diagnosis. Antigen testing of a stool sample can be used to diagnose a rotavirus infection as well as parasitic worm infestations.

The doctor will also usually order a blood test to evaluate the electrolyte levels in the patient's blood in order to assess the need for rehydration.

Imaging studies

Imaging studies (usually CT scans, x rays, or **ultrasound**) may be performed in patients with amebic dysentery to determine whether the lungs or liver have been affected. They may also be used to diagnose schistosomiasis, as the eggs produced by the worms will show up on ultrasound or MRI studies of the liver, intestinal wall, or bladder.

Treatment

Medications are the primary form of treatment for dysentery:

- Bacillary dysentery. Dysentery caused by *Shigella* is usually treated with such antibiotics as trimethoprim-sulfamethoxazole (Bactrim, Septra), nalidixic acid (NegGram), or ciprofloxacin (Cipro, Ciloxan). Because the various species of *Shigella* are becoming resistant to these drugs, however, the doctor may prescribe one of the newer drugs. Patients with bacillary dysentery should not be given antidiarrheal medications, including loperamide (Imodium), paregoric, and diphenolate (Lomotil), because they may make the illness worse.
- Amebic dysentery. The most common drugs given for amebiasis are diloxanide furoate (Diloxide), iodoquinol (Diquinol, Yodoxin), and metronidazole (Flagyl). Metronidazole should not be given to pregnant women but paromomycin (Humatin) may be used instead. Patients with very severe symptoms may be given emetine dihydrochloride or dehydroemetine, but these drugs should be stopped once the patient's symptoms are controlled.
- Dysentery caused by other protozoa. Balantidiasis, giardiasis, and cryptosporidiosis are treated with the same drugs as amebic dysentery; patients with giardiasis resistant to treatment may be given albendazole (Zentel) or furazolidone (Furoxone).
- Viral dysentery. The primary concern in treating viral dysentery, particularly in small children, is to prevent dehydration. Antinausea and antidiarrhea medications should not be given to small children. Probiotics, including *Lactobacillus casei* and *Saccharomyces boulardii*, have been shown to reduce the duration and severity of viral diarrhea in small children by 30–70%.
- Dysentery caused by parasitic worms. Whipworm infestations are usually treated with anthelminthic medications, most commonly mebendazole (Vermox). Schistosomiasis may be treated with praziquantel (Biltricide), metrifonate (Trichlorfon), or oxamniquine, depending on the species causing the infestation.

Newer drugs that have been developed to treat dysentery include tinidazole (Tindamax, Fasigyn), an antiprotozoal drug approved by the Food and Drug Administration (FDA) in 2004 to treat giardiasis and **amebiasis** in adults and children over the age of three years. This drug should not be given to women in the first three months of **pregnancy**. In addition, adults taking tinidazole should not drink alcoholic beverages while using it, or for three days after the end of treatment. The other new drug is nitazoxanide (Alinia), another antiprotozoal medication that has the advantage of lacking the bitter taste of metronidazole and tinidazole.

Fluid replacement is given if the patient has shown signs of dehydration. The most common treatment is an oral rehydration fluid containing a precise amount of salt and a smaller amount of sugar to replace electrolytes as well as water lost through the intestines. Infalyte and Pedialyte are oral rehydration fluids formulated for the special replacement needs of infants and young children.

Surgery

Surgery is rarely necessary in treating dysentery, but may be required in cases of fulminant **colitis**, particularly if the patient's colon has perforated. Patients with liver abscesses resulting from amebic dysentery may also require emergency surgery if the **abscess** ruptures. In some cases exploratory surgery may be needed to determine whether severe abdominal pain is caused by schistosomiasis, amebic dysentery, or **appendicitis**.

Alternatives

There are a number of alternative treatments for dysentery, most of which are derived from plants used by healers for centuries. Because dysentery was known to ancient civilizations as well as modern societies, such alternative systems as **traditional Chinese medicine** (TCM) and **Ayurvedic medicine** developed treatments for it.

Ayurvedic medicine

Ayurvedic medicine recommends fruits and herbs, specifically cumin seed, bael fruit (*Aegle marmelos*, also known as Bengal quince), and arjuna (*Terminalia arjuna*) bark for the treatment of dysentery. Ayurvedic practitioners may also give the patient dietary supplements known as Isabbael, Lashunadi Bati, and Bhuwaneshar Ras. To rehydrate the body, adult patients

WWW.BOOKBAZ.IR

may be given a combination of slippery elm water and barley to drink, at least a pint per day.

Traditional Chinese medicine

To treat dysentery, traditional Chinese doctors use astringent drugs, which are intended to constrict or tighten mucous membranes and other body tissues to slow down fluid loss. Myrobalan fruit (*Terminalia chebula*), nut galls (swellings produced on the leaves and stems of oak trees by the secretions of certain insects), and opium extracted from the opium poppy (*Papaver somniferum*) are the natural materials most commonly used. Paregoric, a water-based solution of morphine that is still used in the West to treat diarrhea, is derived from the opium poppy.

Other plant-based remedies

Researchers in Mexico reported in early 2005 that the roots of *Geranium mexicanum*, a plant that produces a sap traditionally used to treat coughs or diarrhea, contains compounds that are active against both *Giardia lamblia* and *Entamoeba histolytica*. Plant biologists in Africa are studying the effectiveness of African mistletoe (*Tapinanthus dodoneifolius*), a traditional remedy for dysentery among the Hausa and Fulani tribes of Nigeria.

Dietary supplements

A study published in the *American Journal of Clinical Nutrition* in early 2005 reported that supplemental zinc (twice the recommended daily dietary allowance) boosts the body's immune response during acute shigellosis.

Homeopathy

There are at least ten different homeopathic remedies used to treat diarrhea. Contemporary homeopaths, however, distinguish between diarrhea that can be safely treated at home with such homeopathic remedies as *Podophyllum*, *Veratrum album*, *Bryonia*, and *Arsenicum*, and diarrhea that indicates dysentery and should be referred to a physician. Signs of dehydration (loss of normal skin texture, **dry mouth**, sunken eyes), severe abdominal pain, blood in the stool, and unrelieved **vomiting** are all indications that mainstream medical care is required.

Prognosis

Most adults in developed countries recover completely from an episode of dysentery. Children are at greater risk of becoming dehydrated, however; bacillary dysentery in particular can lead to a child's death from dehydration in as little as 12–24 hours.

- Bacillary dysentery. Most patients recover completely from shigellosis, although their bowel habits may not become completely normal for several months. About 3% of people infected by *S. flexneri* will develop Reiter's syndrome, which may lead to a chronic form of arthritis that is difficult to treat. Elderly patients or those with weakened immune systems sometimes develop secondary bacterial infections after an episode of shigellosis.
- Amebic dysentery. Most people in North America who become infected with *E. histolytica* do not become severely ill. Patients who develop a severe case of amebic dysentery, however, are at increased risk for such complications as fulminant colitis or liver abscess. About 0.5% of patients with amebic dysentery develop fulminant colitis, but almost half of these patients die. Between 2% and 7% of cases of amebic liver abscess result in rupture of the abscess with a high mortality rate. Men are 7–12 times more likely to develop a liver abscess than women. Any patient diagnosed with amebic dysentery should have stool samples examined for relapse 1, 3, and 6 months after treatment with medications whether or not they have developed complications.
- Dysentery caused by other protozoa. Cryptosporidiosis may lead to respiratory infections or pancreatitis in patients with AIDS. The risk of these complications, however, is reduced in AIDS patients who are receiving highly active antiretroviral therapy (HAART).
- Viral dysentery. Most people in North America recover completely without complications unless they become severely dehydrated. Viral dysentery in children in developing countries, however, is a major cause of mortality.
- Dysentery caused by parasitic worms. Untreated whipworm infections can lead to loss of appetite, chronic diarrhea, and retarded growth in children. Untreated schistosomiasis can develop into a chronic intestinal disorder in which fibrous tissue, small growths, or strictures (abnormal narrowing) may form inside the intestine. Patients treated for schistosomiasis should have stool samples checked for the presence of worm eggs 3 and 6 months after the end of treatment.

Prevention

The disease agents that cause dysentery do not confer immunity against reinfection at a later date.

KEY TERMS

Anthelminthic (also spelled anthelmintic)—A type of drug or herbal preparation given to destroy parasitic worms or expel them from the body.

Bacillus—A rod-shaped bacterium. One common type of dysentery is known as bacillary dysentery because it is caused by a bacillus.

Enterotoxin—A type of harmful protein released by bacteria and other disease agents that affects the tissues lining the intestines.

Fulminant—Occurring or flaring up suddenly and with great severity. A potentially fatal complication of amebic dysentery is an inflammation of the colon known as fulminant colitis.

Probiotics—Food supplements containing live bacteria or other microbes intended to improve or restore the normal balance of microorganisms in the digestive tract.

Proctoscope—An instrument consisting of a thin tube with a light source, used to examine the inside of the rectum.

Protozoan (plural, protozoa)—A member of the simplest form of animal life, a one-celled organism. Amebic dysentery is caused by a protozoan.

Reiter's syndrome—A group of symptoms that includes arthritis, inflammation of the urethra, and conjunctivitis, and develops as a late complication of infection with *Shigella flexneri*. The syndrome was first described by a German doctor named Hans Reiter in 1918.

Tenesmus—Straining to urinate or defecate without being able to do so. Tenesmus is a characteristic feature of bacillary dysentery.

Trophozoite—The active feeding stage of a protozoal parasite, as distinct from its encysted stage.

There are no vaccines for bacillary dysentery or amebic dysentery; however, a vaccine against schistosomiasis is under investigation. An oral vaccine against **rotavirus infections** was developed for small children but was withdrawn in 2004 because it was associated with an increased risk of small-bowel disorders. Newer vaccines against rotaviruses and caliciviruses are being developed.

Public health measures

Public health measures to control the spread of dysentery include the following:

- Requiring doctors to report cases of disease caused by *Shigella*, *Entamoeba histolytica*, and other parasites that cause dysentery. Careful reporting allows the CDC and state public health agencies to investigate local outbreaks and plan prevention efforts.
- Posting advisories for travelers about outbreaks of dysentery and other health risks in foreign countries. The Travelers' Health section of the CDC website (http://wwwnc.cdc.gov/travel/) is a good source of up-to-date information.
- Instructing restaurant workers and other food handlers about proper methods of hand washing, food storage, and food preparation.
- Instructing workers in day care centers and nursing homes about the proper methods for changing and cleaning soiled diapers or bedding.
- Inspecting wells, other sources of drinking water, and swimming pools for evidence of fecal contamination.

Personal precautions

Individuals can lower their risk of contracting dysentery by the following measures:

- Not allowing anyone in the household who has been diagnosed with amebic or bacillary dysentery to prepare food or pour water for others until their doctor confirms that they are no longer carrying the disease agent.
- Avoiding anal sex or oral-genital contacts.
- Washing the hands carefully with soap and water after using the bathroom, and supervising the handwashing of children in day care centers or those at home who are not completely toilet-trained.
- When traveling, drinking only boiled or treated water, and eating only cooked hot foods or fruits that can be peeled by the traveler.
- Avoiding swimming in fresh water in areas known to have outbreaks of schistosomiasis.

Dysfunctional uterine bleeding

Definition

Dysfunctional uterine bleeding is irregular, abnormal uterine bleeding that is not caused by a tumor, infection, or **pregnancy**.

Description

Dysfunctional uterine bleeding (DUB) is a disorder that occurs most frequently in women at the beginning and end of their reproductive lives. About half the cases occur in women over 45 years of age, and about one-fifth occur in women under age 20.

Dysfunctional uterine bleeding is diagnosed when other causes of uterine bleeding have been eliminated. Failure of the ovary to release an egg during the menstrual cycle occurs in about 70% of women with DUB. This is probably related to a hormonal imbalance.

DUB is common in women who have **polycystic ovary syndrome** (cysts on the ovaries). Women who are on dialysis may also have heavy or prolonged periods. So do some women who use an **intrauterine device** (IUD) for birth control.

DUB is similar to several other types of uterine bleeding disorders and sometimes overlaps these conditions.

Menorrhagia

Menorrhagia, sometimes called hypermenorrhea, is another term for abnormally long, heavy periods. This type of period can be a symptom of DUB, or many other diseases or disorders. In menorrhagia, menstrual periods occur regularly, but last more than seven days, and blood loss exceeds 3 oz (88.7 mL). Passing **blood clots** is common. Between 15–20% of healthy women experience debilitating menorrhagia that

interferes with their normal activities. Menorrhagia may or may not signify a serious underlying problem.

Metrorrhagia

Metrorrhagia is bleeding between menstrual periods. Bleeding is heavy and irregular as opposed to ovulatory spotting which is light bleeding, in mid-cycle, at the time of ovulation.

Polymenorrhea

Polymenorrhea describes the condition of having too frequent periods. Periods occur more often than every 21 days, and ovulation usually does not occur during the cycle.

Causes and symptoms

Dysfunctional uterine bleeding often occurs when the endometrium, or lining of the uterus, is stimulated to grow by the hormone estrogen. When exposure to estrogen is extended, or not balanced by the presence of progesterone, the endometrium continues to grow until it outgrows its blood supply. Then it sloughs off, causing irregular bleeding. If the bleeding is heavy enough and frequent enough, anemia can result.

Menorrhagia is representative of DUB. It is caused by many conditions including some outside the reproductive system. Causes of menorrhagia include:

- adenomyosis (a benign condition characterized by growths in the area of the uterus)
- imbalance between the hormones estrogen and progesterone
- fibroid tumors
- pelvic infection
- endometrial cancer (cancer of the inner mucous membrane of the uterus)
- endometrial polyps
- endometriosis (a condition in which endometrial or endrometrial-like tissue appears outside of its normal place in the uterus)
- use of an intrauterine device (IUD) for contraception
- hypothyroidism
- blood clotting problems (rare)
- lupus erythematosus
- pelvic inflammatory disease
- steroid therapy
- advanced liver disease
- renal (kidney) disease
- chemotherapy (cancer treatment with chemicals)

To diagnose dysfunctional uterine bleeding, many of the potential causes must be eliminated. When all potential causes connected with pregnancy, infection, and tumors (benign or malignant) are eliminated, then menorrhagia is presumed to be caused by dysfunctional uterine bleeding.

Diagnosis

Diagnosis of any menstrual irregularity begins with the patient herself. The doctor will ask for a detailed description of the problem, and take a history of how long it has existed, and any patterns the patient has observed. A woman can assist the doctor in diagnosing the cause of abnormal uterine bleeding by keeping a record of the time, frequency, length, and quantity of bleeding. She should also tell the doctor about any illnesses, including long-standing conditions, like **diabetes mellitus**. The doctor will also inquire about sexual activity, use of contraceptives, current medications, and past surgical procedures.

Laboratory tests

After taking the woman's history, the gynecologist or family practitioner does a pelvic examination and Pap smear. To rule out specific causes of abnormal bleeding, the doctor may also do a pregnancy test and blood tests to check the level of thyroid hormone. Based on the initial test results, the doctor may want to do tests to determine the level of other hormones that play a role in reproduction. A test of blood clotting time and an adrenal function test are also commonly done.

Imaging

Imaging tests are important diagnostic tools for evaluating abnormal uterine bleeding. **Ultrasound** examination of the pelvic and abdominal area is used to help locate **uterine fibroids**, also called uterine leiomyoma, a type of tumor. Visual examination through hysterscopy—where a camera inside a thin tube is inserted directly into the uterus so that the doctor can see the uterine lining—is also used to assess the condition of the uterus.

Hystersalpingography can help outline endometrial polyps and fibroids and help detect **endometrial cancer**. In this procedure an x ray is taken after contrast media has been injected into the cervix. **Magnetic resonance imaging** (MRI) of the pelvic region can also be used to locate fibroids and tumors.

WWW.BOOKBAZ.IR

KEY TERMS

Dilatation and curettage (D & C)—A procedure performed under anesthesia during which the cervix is dilated, and tissue lining the uterus is scraped out with a metal spoon-shaped instrument or a suction tube. The procedure can be either diagnostic, or to remove polyps.

Endometrial biopsy—The removal of tissue either by suction or scraping of samples of tissue from the uterus. The cervix is not dilated. The procedure has a lower rate of diagnostic accuracy than a D & C, but can be done as an office procedure under local anesthesia.

Endometrial cancer—Cancer of the inner mucous membrane of the uterus.

Fibroids, or fibroid tumors—Fibroid tumors are noncancerous (benign) growths in the uterus. They occur in 30–40% of women over age 40, and do not need to be removed unless they are causing symptoms that interfere with a woman's normal activities.

Hypothyroidism—A disorder in which the thyroid gland produces too little thyroid hormone causing a decrease in the rate of metabolism with associated effects on the reproductive system.

Lupus erythematosus—A chronic inflammatory disease in which inappropriate immune system reactions cause abnormalities in the blood vessels and connective tissue.

Progesterone—A hormone naturally secreted by the ovary, or manufactured synthetically, that prepares the uterus for implantation of a fertilized egg.

Prostaglandins—A group of chemicals that mediate, or determine the actions of other chemicals in the cell or body.

Invasive procedures

Endometrial biopsy (the removal and examination of endometrial tissue) is the most important testing procedure. It allows the doctor to sample small areas of the uterine lining, while cervical biopsy allows the cervix to be sampled. Tissues are then examined for any abnormalities.

Dilatation and curettage (D & C), once common is rarely done today for diagnosis of DUB. It is done while the patient is under either general or regional **anesthesia**. Women over 30 are more likely to need a D & C, as part of the diagnostic procedure, than younger women.

Because DUB is diagnosed by eliminating other possible disorders, diagnosis can take a long time and involve many tests and procedures. Older women are likely to need more extensive tests than adolescents because the likelihood of reproductive cancers is greater in this age group, and must be definitively eliminated before treating bleeding symptoms.

Treatment

Treatment of DUB depends on the cause of the bleeding and the age of the patient. When the underlying cause of the disorder is known, that disorder is treated. Otherwise the goal of treatment is to relieve the symptoms to a degree that uterine bleeding does not interfere with a woman's normal activities or cause anemia.

Generally the first approach to controlling DUB is to use **oral contraceptives** that provide a balance between the hormones estrogen and progesterone. Oral contraceptives are often very effective in adolescents and young women in their twenties. NSAIDs (**nonsteroidal anti-inflammatory drugs**), like Naprosyn and Motrin, are also used to treat DUB.

When bleeding cannot be controlled by hormone treatment, surgery may be necessary. Dilatation and curettage sometimes relieves the symptoms of DUB. If that fails, endometrial ablation removes the uterine lining, but preserves a woman's uterus. This procedure is sometimes be used instead of **hysterectomy**. However, as it affects the uterus, it can only be used when a woman has completed her childbearing years. The prescription of iron is also important to decrease the risk of enemia.

Until the 1980s, hysterectomy often was used to treat heavy uterine bleeding. Today, hysterectomy is used less frequently to treat DUB, and then only after other methods of controlling the symptoms have failed. A hysterectomy leaves a woman unable to bear children, and, therefore, is limited largely to women who are unable to, or uninterested in, bearing children. Still, hysterectomy is a common treatment for long-standing DUB in women done with childbearing.

Alternatives

Alternative practitioners concentrate on good **nutrition** as a way to prevent heavy periods that are

not caused by uterine fibroids, endometrial polyps, **endometriosis**, or cancer. Iron supplementation (100 mg per day) not only helps prevent anemia, but also appears to reduce menorrhagia in many women. Other recommended dietary supplements include **vitamins** A and C. Vitamin C improves capillary fragility and enhances iron uptake.

Vitamin E and bioflavonoid supplements are also recommended. Vitamin E can help reduce blood flow, and bioflavonoids help strengthen the capillaries. **Vitamin K** is known to play a role in clotting and is helpful in situations where heavy bleeding may be due to clotting abnormalities.

Botanical medicines used to assist in treating abnormal bleeding include spotted cranesbill (*Geranium maculatum*), birthroot (*Trillium pendulum*), blue cohosh (*Caulophyllum thalictroides*), witch hazel (*Hamamelis virginiana*), shepherd's purse (*Capsella bursa-pastoris*), and yarrow (*Achillea millifolia*). These are all stiptic herbs that act to tighten blood vessels and tissue. Hormonal balance can also be addressed with herbal formulations containing phytoestrogens and phytoprogesterone.

Prognosis

Response to treatment for DUB is highly individual and is not easy to predict. The outcome depends largely on the woman's medical condition and her age. Many women, especially adolescents, are successfully treated with hormones (usually oral contraceptives). As a last resort, hysterectomy removes the source of the problem by removing the uterus, but this operation is not without risk, or the possibility of complications.

Prevention

Dysfunctional uterine bleeding is not a preventable disorder.

Dyslexia

Definition

Dyslexia is a learning disability noted for spatial reversals and shifts. It is characterized by problems in reading, spelling, writing, and sometimes math. In many cases, dyslexia appears to be inherited.

Demographics

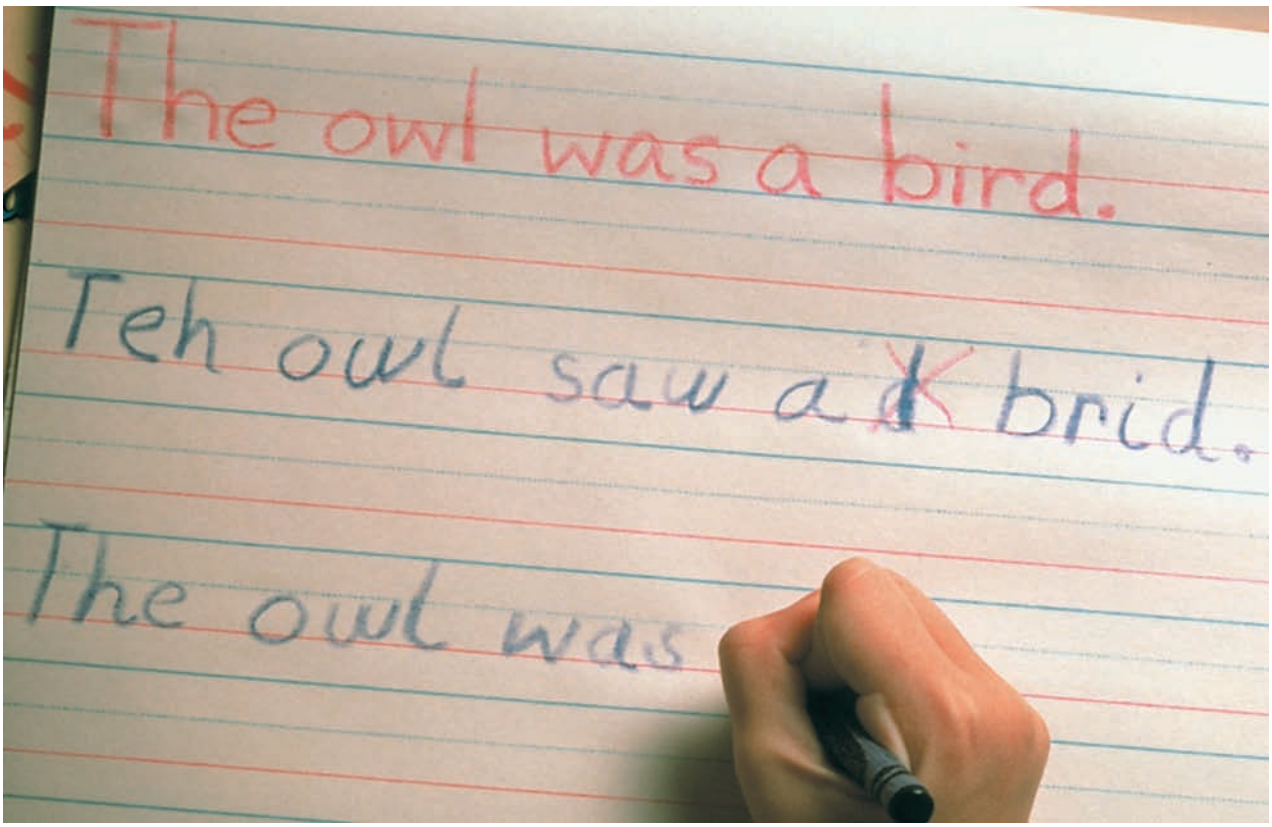
Estimates of people with dyslexia range from 2–15% of the United States population. Most research studies give a figure of 5%. Originally it was thought that dyslexia affected more boys than girls (in a ratio of 5:1), but later studies found boys to be only slightly more likely than girls to be dyslexic. Figures for diagnosed child dyslexics are skewed because for various reasons boys tend to be referred more frequently for special education. Diagnosis is complicated by the fact that anywhere from 20–55% of dyslexics also have attention deficit/hyperactivity disorder (**ADHD**), a behavioral disorder that may aggravate reading problems.

Description

Dyslexia is a specific learning disability characterized by a significant disparity between an individual's general intelligence and his or her language skills, usually reflected in school performance. The word dyslexia is derived from the Greek word, *dys* (meaning poor or inadequate) and the word *lexis* (meaning words or language). The term was coined in 1887 by German physician Rudolf Berlin who published a case study of a young boy who had difficulties with reading and writing in spite of having normal intelligence. In 1896, W. Pringle Morgan, a British doctor, published the first English-language case study of dyslexia. It concerned a 14-year-old boy who had not yet learned to read, even though his other intellectual abilities were well within the normal range.

Most individuals with dyslexia have average or above average intelligence, and it is speculated that they have heightened visual-spatial and motor awareness. Many famous inventors, artists, and other creative people have had dyslexia; Thomas Edison, Albert Einstein, Winston Churchill, Michael Faraday, Woodrow Wilson, Guglielmo Marconi, General George Patton, and Auguste Rodin are all thought to have been dyslexic.

WWW.BOOKBAZ.IR



A student with dyslexia has difficulty copying words. *(Will & Deni McIntyre/Science Source/Photo Researchers, Inc.)*

Risk factors

Dyslexia is believed to be strongly familial. About 40% of boys and 20% of girls with a dyslexic parent develop the disorder. Dyslexia is believed to occur equally in all races.

Causes and symptoms

There are many different theories about the causes and classifications of different types of dyslexia, but few hard conclusions. It is generally agreed that there is a strong hereditary component of dyslexia. Several genetic studies have found gene linkages on chromosomes 1 and 6 that demonstrate heterogeneous (multiple methods of) transmission. Four specific genes linked to dyslexia have been identified, and all four participate in brain development. **Positron emission tomography** (PET) studies have shown that dyslexics assigned reading tasks show a lower level of activity than children with normal reading skills in a part of the brain known as the left inferior parietal cortex, a region that is necessary for the rapid perception of word forms. Studies using functional **magnetic resonance imaging** (fMRI) pinpointed the left inferior frontal gyrus, the left inferior parietal lobule, and the left middle temporal gyrus as areas of low activation in dyslexic children given word tests to complete. Another indication that specific areas of the brain are involved in dyslexia comes from case studies of children who have suffered **stroke**. In one study reported in 2006, a six-year-old boy had suffered a stroke affecting the left hemisphere of his brain. He was able to read words that he had learned prior to the stroke, but attempts to read unfamiliar words were unsuccessful until he received special training.

The most obvious symptoms of the dyslexic show up in reading and writing; however, listening, speaking, and general organizational skills are also affected. The individual with dyslexia may have trouble transferring information across modalities, for example from verbal to written forms. The dyslexic's characteristic reversal of letters, confusion between such similar letters as "b" and "d," omission of words when reading aloud, trouble sounding out words, and difficulty following written instructions were first thought to be the result of vision and perceptual problems—that is, a failure of taking in the stimulus. Only a small percentage of dyslexics have vision disorders, however, and it

is now generally agreed by physicians, researchers, and educators that dyslexia is primarily a language disorder. Whereas the non-dyslexic intuitively learns phonic (sound) rules while learning to read, the dyslexic needs specific and methodical drills and practice to learn the visual-auditory associations necessary for reading comprehension and written expression.

The most common symptoms of dyslexia include:

- lack of awareness of sounds
- delayed speech
- difficulty understanding spoken words
- difficulty reading single words
- extreme difficulty spelling words
- extreme difficulty with handwriting
- difficulty with locational and time indicators: up/down, right/left, yesterday/tomorrow
- lack of enjoyment in reading
- difficulty transferring information across modalities: writing down thoughts or speech, reading out loud

Diagnosis

Anyone who is suspected to have dyslexia should have a comprehensive evaluation, including hearing, vision, and intelligence testing. The test should include all areas of learning and learning processes, not just reading.

Children and adults are usually referred for testing for dyslexia because of repeated problems in school or work settings. As further research pinpoints the genes responsible for some cases of dyslexia, there is a possibility that earlier testing will be established to allow for early interventions. Earlier interventions could help to prevent the negative educational outcomes that can be associated with dyslexia.

Tests

Children who demonstrate a reading level greater than two SEs below expected level for their age, intelligence, and education are generally diagnosed as dyslexic. Once reading problems are identified, a comprehensive series of tests of neuropsychological function (vision, hearing, and speech), intelligence, and achievement (word and letter recognition) will determine the existence of visual and auditory problems, behavior problems, or subnormal intelligence, all of which may have symptoms similar to dyslexia. Because children of different ages have different levels of normal language skill, the specific tests used will differ by age group.

A child normally develops phonological awareness—the ability to differentiate between speech sounds and recognize their written symbols—while learning to read. The ability to sound out nonsense words (for example, the lines from Lewis Carroll's poem "Jabberwocky": "Twas brillig and the slithy toves/ Did gyre and gimble in the wabe") is a strong indicator of phonological awareness. In cases in which the dyslexic has compensated for the disability by paying special attention to context or simply by rote memorization, a nonsense-word test may reveal the reader's underlying phonological disability despite his academic success.

While teachers and physicians are trained to recognize some language problems, many symptoms of dyslexia will be noticeable to parents. Contrary to popular thought, a child's mirror writing (writing backwards), reversal of letters, and confusion over which hand to use are not definitively signs of dyslexia, and may only indicate lack of development.

Treatment

If caught early, especially before the third grade, dyslexia is highly treatable through special education. Dyslexia is categorized as a learning disability under the national Education for All Handicapped Children Act passed in 1975. Dyslexic children are entitled to a comprehensive evaluation by a team of educational specialists, to an individualized education plan (IEP), and to ongoing evaluation under the terms of the federal Individuals with Disabilities Education Act (IDEA), first passed in 1990 and amended in 2004. Parents or caretakers may request the initial evaluation, may participate in all levels of the process, and must give their consent before the treatment plan begins.

Traditional

There are many treatment approaches available to the public, ranging from visual stimulation to **diets** to enhancement of regular language education. But it is generally agreed that specialized education is the only successful remedy, and the American Academy of Ophthalmology, the American Academy of Pediatrics, and the American Association for Pediatric Ophthalmology and **Strabismus** have issued a policy statement warning against visual treatments and recommending a cross-disciplinary educational approach. In fact, the first researcher to identify and study dyslexia, Dr. Samuel Torrey Orton, developed the core principles of such an approach in the 1920s. The work of three of his followers—Bessie Stillman, Anna Gillingham, and Beth Slingerland—underlies many of the

WWW.BOOKBAZ.IR

programs in wide use today such as project READ, the Wilson Reading System, and programs based on the Herman method. These and other successful programs have three characteristics in common. They are:

- Sound/symbol based. They break words down into their smallest visual components: letters and the sounds associated with them.
- Multisensory. They attempt to form and strengthen mental associations among visual, auditory, and kinesthetic channels of stimulation. The student simultaneously sees, feels, and says the sound-symbol association; for example, a child may trace the letter or letter combination with his finger while pronouncing a word out loud.
- Highly structured. Remediation begins at the level of the single letter-sound, works up to digraphs, then syllables, then into words and sentences in a very systematic fashion. Repetitive drill and practice serve to form necessary sound-symbol associations.

Whatever remediation program is used, the IEP itself should define the student's specific problems and learning objectives, rather than make vague or general recommendations such as "John needs more support in reading comprehension." A good example of a specific learning objective would be "Max will be able to identify the following sound/symbol association in nonsense words: consonants, short and long vowels, and blends." When ADD is co-diagnosed with dyslexia, special care should be taken to identify specific reading problems and to define cognitive as well as behavioral learning objectives.

Drugs

Treatment for dyslexia can sometimes include use of anti-motion drugs, addressing the symptoms of balance and coordination that results from visual perception alterations; stimulant drugs, such as pemoline (Cylert) or methylphenidate (Ritalin), to address symptoms of low self esteem, restlessness, and distractibility, and 'nootropics' drugs, a class of drugs believed to improve cognitive function. The stimulant drugs may be more effective for **learning disorders** related to ADHD or ADD than for dyslexia. The drug piracetam (Nootropil), a nootropic, although reported as a possible treatment for dyslexia, is also reported to have legal issues because it has not been approved for use in the United States by the Food and Drug Administration (FDA).

Reported potential side effects of the stimulants include nervousness and **insomnia**, and are contraindicated with **epilepsy**, **allergies**, blood pressure problems, or with use of monoamine oxidase (MAO) inhibitors. Long-term use of stimulants in children are reported to adversely affect growth, may ironically depress the nervous system or lead to loss of consciousness. By reducing natural levels of stimulants in the brain, they may also cause dependence. The stimulants and nootropics are said to increase the effects of alcohol and amphetamines. Other possible interactions include use of anti-convulsants or anti-epileptics; tricyclic anti-depressants; anti-coagulants, like Coumadin; and "atropine-like drugs" that blocks the neurotransmitter acetylcholine.

Alternatives

Ronald D. Davis, writing in *The Gift of Dyslexia* outlines an alternative and complementary treatment consistent with the "moving point of view" model. According to this model, and the reason why letters seem to change shape and float, why lines of print appear to move, and why words appear to be other than they are is that the dyslexic individual sees the world predominantly through his or her "mind's eye," rather than through his or her physiologic eye. In other words, people with dyslexia more than all others, sees what they 'think' they see, rather than what their eyeballs see. To further complicate matters, they do this so quickly that they easily become confused when the multiple facets do not produce a solid view.

The object of treatment proposed by Ronald Davis, a dyslexic individual himself, is to train the mind's eye to return to a learned, anchored, viewpoint when they realize they are seeing with their mind, and not with their eyeballs. This is accomplished with assessment testing, followed by one-on-one exercises that retrain mental perception pathways. Using the gifts of the dyslexic individual—their imagination and curiosity—these exercises involve creative physical activities, including the use of modeling clay, "koosh" balls, and movement training. Davis founded the Reading Research Council's Dyslexia Correction Center in 1982, and the Davis Dyslexia Association International, which trains educators and therapists, in 1995.

Prognosis

If left unaddressed, a person with dyslexia may become "functionally illiterate," able to function limited by their ability to read, spell, have their handwriting understood, or do arithmetic. Recognizing that dyslexia is a developed learning disorder affecting people of extraordinary curiosity, imagination and intelligence—people of genius, often—from a productive or functional point of view, dyslexia may contribute significantly, positively or negatively, to

KEY TERMS

Attention deficit disorder (ADD)—A learning disability characterized by an inability to pay attention. It may be different from dyslexia in that dyslexic individuals are highly aware and able to pay attention, but unable to make sense of their perceptions.

Attention deficit hyperactivity disorder (ADHD)—A learning disability characterized by an inability to sit still or concentrate well. It has been demonstrated to be diagnostically different from dyslexia by speech and vocalization patterns.

Monoamine oxidase (MAO) inhibitors—A group of anti-depressant drugs.

Neurotransmitter—A chemical substance that facilitates the passing of messages along nerve pathways. There are several different neurotransmitters used in the human nervous system, each with distinct effects on mood, movement and perception.

Point of view—In a person with dyslexia, this term is used to describe the angle from which their mind's eye views an object. This point of view may be unanchored and moving about, as if several different people were telling what they see all at the same time.

performance levels. From an emotional or psychological point of view, dyslexia affects self esteem, and promotes confusion and frustration, that may contribute to under achievement.

Many people with dyslexia become very successful. The eventual outcome for an individual with dyslexia depends on a wide variety of factors, including severity of the disorder, age of diagnosis, and achievement level in other non-language areas. Early diagnosis and intervention are important in improving long-term outcomes.

Prevention

There is no known way to prevent dyslexia.

Dysmenorrhea

Definition

Dysmenorrhea is the occurrence of painful cramps during a woman's menstrual period. The English word comes from three Greek words that mean "painful," "month," and "flow." Most women experience some discomfort during their periods; however, dysmenorrhea is diagnosed when the **pain** is so severe as to limit the woman's normal activities or require medical or surgical treatment.

Demographics

Dysmenorrhea is by definition a disorder that affects only females of childbearing age. Some studies

WWW.BOOKBAZ.IR

indicate that the rate of dysmenorrhea is highest among adolescents and young adults, and declines with age. Survey results are highly variable, ranging from 29% in one family practice setting to 90% in a group of Swedish adolescents. One group of researchers reported that 67% of teenagers in their sample reported dysmenorrhea, compared to 27% of women in their 30s. Primary dysmenorrhea is the leading cause of recurrent short-term absence from school among adolescent American girls. In the workplace, dysmenorrhea causes 600 million missed work hours in the United States each year and an economic loss of $2 billion.

Secondary dysmenorrhea is more common in older women than in teenagers; in general, women who experience dysmenorrhea for the first time after age 25 have secondary dysmenorrhea.

As far as is known as of 2014, race or ethnicity is not a risk factor for dysmenorrhea.

Description

Women with dysmenorrhea describe the pain in their abdomens as variously shooting, stabbing, burning, sharp, throbbing, or nauseating. Dysmenorrhea may precede the onset of the woman's period by several days, or accompany it. It usually subsides as the woman's flow tapers off.

In some women, dysmenorrhea is accompanied by unusually heavy blood loss—a condition known as menorrhagia.

Risk factors

The likelihood that a woman will have painful cramps increases if she:

- has a family history of painful periods
- leads a stressful life
- smokes
- has never borne a child
- is below 20 years of age
- began puberty before age 11
- has heavy periods
- doesn't get enough exercise
- drinks large quantities of beverages containing caffeine (coffee, tea, cola, energy drinks)
- has attempted to lose weight rapidly
- has pelvic inflammatory disease (PID)
- has a history of sexual abuse

Causes and symptoms

Dysmenorrhea is called "primary" when there is no specific abnormality, and "secondary" when the pain is caused by an underlying gynecological problem. It is believed that primary dysmenorrhea occurs when prostaglandins, hormone-like substances produced by uterine tissue, trigger strong muscle contractions in the uterus during menstruation. However, the level of prostaglandins does not seem to correlate with how strong a woman's cramps are. Some women have high levels of prostaglandins and no cramps, whereas other women with low levels have severe cramps. This is why experts assume that cramps must also be related to other causes, such as **diets**, genetics, **stress**, and different body types, in addition to prostaglandins. The first year or two of a girl's periods are not usually very painful. However, once ovulation begins, the blood levels of the prostaglandins rise, leading to stronger contractions.

Secondary dysmenorrhea may be caused by **endometriosis**, fibroids, **ovarian cysts**, an **ectopic pregnancy**, or an infection in the pelvis.

Symptoms of dysmenorrhea include a dull, throbbing cramping in the lower abdomen that may radiate to the lower back and thighs. In addition, some women may experience **nausea and vomiting**; **diarrhea** or **constipation**; hypersensitivity to lights, sounds, or odors; general irritability and **fatigue**; heavy sweating; or **dizziness**. Cramps usually last for two or three days at the beginning of each menstrual period. Many women often notice their painful periods disappear after they have their first child, probably due to the stretching of the opening of the uterus or because the birth improves the uterine blood supply and muscle activity, although other women do not notice a change in their level of menstrual discomfort after **childbirth**.

Diagnosis

A doctor should perform a thorough **pelvic exam** and take a patient history to rule out any underlying condition that could cause unusually painful cramps. The patient history will include such information as the patient's age at the time of her first period, family history of painful periods, sexual activity (if any), method of **contraception** used (if any), number of children, the regularity of the menstrual cycle, the cycle's length, date of the last menstrual period, and duration and amount of menstrual flow.

Examination

An office examination of the patient's abdomen is usually sufficient in adolescents who have not been

KEY TERMS

Cervix—The neck or lower narrow portion of the uterus that opens into the upper end of the vagina.

Ectopic pregnancy—A pregnancy in which the fertilized egg has implanted outside the uterus, most often in the Fallopian tubes, although in some cases the pregnancy implants in the ovary or in the abdomen. A ruptured ectopic pregnancy is a medical emergency.

Endometrioma—A type of cyst formed when endometrial tissue grows within the ovary.

Endometriosis—The growth of uterine tissue outside the uterus.

Fibroids—Benign (noncancerous) growths that arise from the smooth muscle layer and connective tissue of the uterus. They sometimes cause secondary dysmenorrhea.

Hormone—A chemical messenger secreted by a gland and released into the blood, where it travels to distant cells to exert an effect.

Hysterectomy—Surgical removal of the entire uterus.

Menorrhagia—Unusually heavy or prolonged menstrual period. It may or may not be associated with dysmenorrhea.

Ovary—One of the two almond-shaped glands in the female body that produces the hormones estrogen and progesterone.

Ovulation—The monthly release of an egg from an ovary.

Progesterone—The hormone produced by the ovary after ovulation that prepares the uterine lining for a fertilized egg.

Uterus—The female reproductive organ that contains and nourishes a fetus from implantation of the fertilized egg until birth.

sexually active. Women who are sexually active should have a pelvic examination.

Tests

There are no laboratory tests that can be used to diagnose primary dysmenorrhea; however, the doctor may order a blood test to rule out a systemic infection, or take a smear of the cervix to evaluate the patient for a sexually transmitted disease.

If the abdominal and pelvic examinations suggest secondary dysmenorrhea, an **ultrasound** of the pelvis is the next step in evaluating endometriosis or ovarian cysts as possible causes of the dysmenorrhea. Other imaging studies that can be used include CT scans and MRIs.

Procedures

The doctor may recommend either a **hysteroscopy** or a **laparoscopy** to check for such causes of secondary dysmenorrhea as fibroids, ovarian cysts, endometriosis, or an ectopic **pregnancy**. In a hysteroscopy, the doctor inserts a thin lighted tube called an endoscope into the uterine cavity. The doctor can remove a small sample of uterine tissue for biopsy as well as examining the interior of the uterus visually. In a laparoscopy, the doctor makes small incisions in the skin of the abdomen and inserts an endoscope with a small camera lens. Laparoscopy can also be used for surgical removal of endometriomas, which are a type of cyst formed when endometrial tissue grows inside the ovaries rather than in the uterus. In extreme cases, the doctor may recommend a hysterectomy—surgical removal of the entire uterus.

A qualified physician is required in order to fit a woman with the Mirena (an **intrauterine device**). The woman's cervix must be dilated before insertion; the process is uncomfortable, and some doctors use a local anesthetic to reduce discomfort.

Treatment

Traditional

DRUGS. Several over-the-counter medications can lessen or completely eliminate the pain of primary dysmenorrhea. Most popular are the **nonsteroidal anti-inflammatory drugs** (NSAIDs), which prevent or decrease the formation of prostaglandins. These include **aspirin**, ibuprofen (Advil), and naproxen (Aleve). For more severe pain, prescription-strength ibuprofen (Motrin) is available. These drugs are usually begun at the first sign of the period and taken for a day or two. Although NSAIDs are effective in providing short-term relief from cramps, some researchers think that long-term use of these medications increases the risk of side effects, particularly diarrhea and peptic ulcer.

If an NSAID is not available, **acetaminophen** (Tylenol) may also help ease the pain. Heat applied to the painful area may bring relief, and a warm bath twice a day also may help.

WWW.BOOKBAZ.IR

Hormonal therapy is another approach to dysmenorrhea that works for many women, although it involves prescription medications rather than over-the-counter pain relievers. Birth control pills and Depo-Provera, an injected contraceptive that must be given every 3 months, work by preventing ovulation. Depo-Provera is also given as a treatment for endometriosis as well as contraception.

Studies of a drug patch containing glyceryl trinitrate to treat dysmenorrhea suggest that it also may help ease pain. This drug has been used in the past to ease preterm contractions in pregnant women. One common side effect of the patch is **headache**.

In 2002, an intrauterine device (IUD) was introduced to help eliminate the pain of menstrual cramps related to endometriosis. The IUD, known as Mirena, is approved for use in the United States as a contraceptive. The device works by releasing small amounts of progestin (a hormone) as well as preventing a fertilized egg from implanting in the lining of the uterus. Mirena cannot be used by women with a history of **pelvic inflammatory disease**, current **gonorrhea** or chlamydia infection, or cervical or **breast cancer**.

There are two drugs that can be given to completely suppress menstrual periods—danazol (Danocrine) and leuprolide acetate (Lupron). These are generally regarded as treatments of last resort for secondary dysmenorrhea that is not helped by other medications. Both Danocrine and Lupron are expensive drugs with severe side effects.

Alternatives

There are a variety of alternative therapies for dysmenorrhea. As of 2014, however, most of these have not been well studied.

NUTRITIONAL THERAPY. The following dietary changes may help prevent or treat menstrual pain:

- Increased dietary intake of foods such as fiber, calcium, soy foods, fruits and vegetables.
- Decreased consumption of foods that exacerbate PMS. They include caffeine, salt and sugar.
- Quitting smoking. Smoking has been found to worsen cramps.
- Taking daily multi-vitamin and mineral supplements that contain high doses of magnesium and vitamin B_6 (pyridoxine), and flaxseed or fish oil supplements. Recent research suggests that vitamin B supplements, primarily vitamin B_6 in complex, magnesium, calcium, zinc, vitamin E, and fish oil supplements (omega-3 fatty acids) also may help relieve cramps.

HERBAL THERAPY. An herbalist may recommend one of the following herbal remedies for menstrual pain:

- Chasteberry (*Vitex agnus-castus*) for women who also experience breast pain, irregular periods, and ovarian cysts.
- Dong quai (*Angelica sinensis*) for women with typical menstrual pain.
- Licorice (*Glycyrrhiza glabra*) for abdominal bloating and cramping.
- Black cohosh (*Cimifuga racemosa*) for relief of menstrual pain as well as mood swing and depression.

PHYSICAL EXERCISE. Several **yoga** positions are popular as methods to ease menstrual pain. In the "cat stretch" position, the woman rests on her hands and knees, slowly arching the back. The pelvic tilt is another popular yoga position, in which the woman lies with knees bent, and then lifts the pelvis and buttocks.

Exercise may be a way to reduce the pain of menstrual cramps through the brain's production of endorphins, the body's own painkillers.

OTHER REMEDIES. Acupuncture and Chinese herbs are other popular alternative treatments for cramps. There are particular formulas depending on the pattern of imbalance. **Aromatherapy** and massage may ease pain for some women. Transcutaneous **electrical nerve stimulation** (TENS) has been touted as a safe and practical way to relieve the pain of dysmenorrhea. It works by using electrodes to stimulate nerve fibers. Some women find relief through visualization, concentrating on the pain as a particular color and gaining control of the sensations. Others find that imagining a white light hovering over the painful area can actually lessen the pain for brief periods. Simply changing the position of the body can help ease cramps. The simplest technique is assuming the fetal position with knee pulled up to the chest while hugging a heating pad or pillow to the abdomen. Also, orgasm can make a woman feel more comfortable by releasing tension in the pelvic muscles.

Prognosis

Dysmenorrhea is a treatable condition with a good-to-excellent prognosis in most women. Most adolescents with primary dysmenorrhea outgrow their painful cramps as they enter their 20s and 30s. Older women with secondary dysmenorrhea usually do well after surgery to remove fibroids or endometriomas;

some of these procedures can be done in outpatient surgical clinics. A complete **hysterectomy** is usually done as an inpatient procedure, but most women recover without complications.

Prevention

Most of the causes of secondary dysmenorrhea cannot be prevented. However, avoidance of **caffeine**, alcohol, and sugar prior to the onset of the period, and NSAIDs taken a day before the period begins may eliminate cramps for some women with primary dysmenorrhea.

Dyspareunia

Definition

Dyspareunia is painful sexual intercourse in women. It is **pain** in the genitals or pelvis that is persistent or recurrent and is experienced at any time before, during, or following sexual intercourse. Dyspareunia usually results from a physical problem but can also stem from psychological difficulties.

Demographics

About 20% of women experience pain with intercourse at some point in their lives and it is estimated that 1–2% of women suffer from dyspareunia. However the true incidence may be higher since many women with dyspareunia do not seek help. The incidence of dyspareunia is significantly higher in women who have been raped or otherwise sexually abused.

Description

There are two types of dyspareunia. Primary dyspareunia begins with the onset of sexual activity and persists. Acquired or secondary dyspareunia occurs after some period of normal sexual function. Occasional discomfort or pain during intercourse is not unusual and is not considered to be dyspare.

The American Psychiatric Association's *Diagnostic and Statistical Manual of Mental Disorders*, fourth edition, text revised (*DSM-IV-TR*), classifies

WWW.BOOKBAZ.IR

dyspareunia as a **sexual dysfunction**. However this listing is controversial, and some practitioners argue that it should be reclassified as a pain disorder in *DSM-V*.

The pain associated with dyspareunia may be confined to the genitals or can be located anywhere within the pelvis. Women with dyspareunia often have **vaginismus**, an involuntary tightening or spasm of the vaginal muscles in response to penetration, which can make intercourse painful or impossible.

Dyspareunia can cause embarrassment or shame. It can lead to relationship problems and may cause a woman to avoid sexual relationships altogether.

Risk factors

Risk factors for dyspareunia include:

- infection or another medical problem
- certain medications, such as antidepressants or high blood pressure medicines
- depression or anxiety
- emotional or psychological stress, especially with regard to a woman's relationship with her sexual partner
- a history of sexual abuse

Causes and symptoms

Primary dyspareunia can result from psychosocial as well as physical factors. Once a woman associates sex with pain, she may find it difficult to relax and become aroused, leading to dyspareunia:

- Prior sexual trauma—such as rape or childhood sexual abuse—can cause dyspareunia. Even when a woman later desires sex, the act of intercourse may trigger memories of the trauma and interfere with her enjoyment. Vaginismus is common in such situations.
- Misinformation or lack of information about sex, a belief that sex is wrong or evil, or fear of sex can lead to dyspareunia.
- A painful initial sexual experience can cause a woman to associate sex with pain.
- Guilt, anxiety, tension, or fear of pregnancy can prevent sexual arousal and cause the vaginal muscles to tense.

Secondary dyspareunia also can have both physical and psychological causes. A clear physical cause for dyspareunia can be identified in about 30–40% of women who consult a sex counselor for this condition. Dyspareunia in postmenopausal women usually results from lack of natural lubrication due to low estrogen levels. Estrogen deficiency can also cause dyspareunia after **childbirth** or while **breastfeeding**. Conditions that affect the skin around the vagina may cause pain during the insertion of a tampon, or even while sitting or wearing pants, as well as during sexual intercourse. Other physical causes of secondary dyspareunia include:

- lack of foreplay, causing vaginal dryness
- a yeast, vaginal, or urinary tract infection
- herpes sores, genital warts, or other sexually transmitted infections (STIs)
- inflammation of the vagina
- vulvar vestibulitis, an unexplained stinging or burning around the opening of the vagina
- eczema or other skin problems in the genital area
- genital irritation from soaps, detergents, douches, or feminine hygiene products
- injury to the vagina and/or surrounding tissues from an accident, pelvic surgery, female circumcision, or episiotomy, which can also cause vaginismus
- intercourse too soon after surgery or childbirth
- an improperly fitted diaphragm or cervical cap for birth control
- an allergic or other reaction to a birth control product such as foams, jellies, or a latex diaphragm or condom
- certain medications that may decrease sexual desire or arousal and natural lubrication, including antidepressants, high blood pressure medications, sedatives, antihistamines, or certain birth control pills

Pain that is felt deep in the pelvis, that occurs with deep penetration, that occurs only in certain positions, or that occurs with orgasm can result from lack of arousal or tension, but is much more likely to be indicative of a medical problem such as:

- fibroid growths in the uterus
- a tipped uterus
- a prolapsed uterus—a uterus that has slipped into the vagina—or a retroverted uterus
- infections in the cervix, uterus, or fallopian tubes
- an ovarian infection or certain other ovarian conditions such as cysts, especially if the pain is experienced only in certain sexual positions
- past surgery resulting in scar tissue, such as a hysterectomy
- endometriosis
- pelvic inflammatory disease
- cystitis
- irritable bowel syndrome

KEY TERMS

Estrogen—A female hormone produced by the ovaries that stimulates the growth of the lining of the uterus.

Sexually transmitted infection (STI)—An infectious disease that is transmitted through sexual activity.

Vaginismus—A painful spasmodic vaginal contraction.

Vulvar vestibulitis—A localized inflammation of the vestibule—the region immediately surrounding the opening of the vagina and the urethra.

- hemorrhoids
- radiation or chemotherapy treatments for cancer

Vasocongestion—the unrelieved accumulation of blood in the dilated blood vessels—can cause dyspareunia. The pelvic area normally becomes congested with blood during sexual arousal. Orgasm quickly relieves this congestion. Dyspareunia from vasocongestion can occur when frequent arousal does not result in orgasm.

Psychological factors that can interfere with arousal and lead to painful intercourse include:

- anxiety or depression that leads to loss of interest in sex
- concerns about one's physical appearance
- fear of intimacy
- stress, which can affect the muscles of the pelvic floor
- relationship problems, including an abusive or emotionally distant sexual partner, loss of attraction to a partner, or fear that a partner has lost interest

Like the causes of dyspareunia, symptoms can vary greatly. The most common symptom of dyspareunia is pain at the vaginal opening as the penis enters the vagina. Entry may be difficult and the pain may be sharp or burning. The vagina may feel very dry; however, the pain often occurs only upon initial penetration. Pain deep within the pelvis can resemble menstrual cramps. The pain may eventually ease or may continue throughout intercourse or as long as thrusting continues. Vasocongestion can cause an aching pain in the pelvic region that persists for hours after intercourse. Some women experience pain only with particular partners or under certain circumstances.

Diagnosis

Examination

A complete medical and sexual history and a gynecological exam including a **pelvic exam** may be necessary to determine the physical cause of dyspareunia. The type and location of the pain and the circumstances under which it occurs can be important clues as to the underlying cause. The examination should include questions about sexual activities as they relate to the pain. A psychological evaluation can help identify possible psychosocial causes for the disorder. Women who have been raped or abused may suffer from **post-traumatic stress disorder** (PTSD) or **generalized anxiety disorder** as well as dyspareunia.

Tests

Laboratory tests may be performed to test for yeast, bacterial, or other types of infection, including STIs. Urine or **allergy tests** may also be performed.

Procedures

In some cases a **pelvic ultrasound** or **laparoscopy** may be necessary to determine the physical cause underlying dyspareunia. Laparoscopy is a procedure in which a slender instrument called a laparoscope is used to view the pelvic organs.

Treatment

Traditional

Treatment of dyspareunia involves addressing the underlying problem, whether it is physical, psychological, or emotional. Dyspareunia can usually be treated by personal changes or medications. Only rarely is surgery required to treat an underlying problem.

Women whose dyspareunia is accompanied by vaginismus may be given a set of devices to use at home to dilate the vaginal opening. These aides retrain the vaginal muscles and help prevent the involuntary muscle tightening that is characteristic of vaginismus. Starting with a very small device, the woman uses progressively larger devices as she overcomes her pain or fear, eventually working up to a penis–sized device.

Counseling can be helpful for identifying and reframing negative feelings about sex. Women who have been abused or raped may benefit from counseling techniques that are designed to help overcome the fears

WWW.BOOKBAZ.IR

and issues resulting from traumatic experiences. Couples therapy can improve communication between partners and resolve problems that may be affecting their sexual relationship. **Sex therapy** can provide information about the physical aspects of arousal and orgasm. A sex therapist will offer suggestions for improving sexual techniques. For example increased foreplay and allowing the woman to control the timing and method of penetration may help her relax and become more easily aroused.

Drugs

There are no specific medications for treating dyspareunia:

- Antibiotics or antiviral drugs may be required for urinary tract infections, STIs, or vaginal infections.
- Over-the-counter or prescription estrogen creams, tablets, or a flexible vaginal ring can often relieve dyspareunia in postmenopausal women.
- A medication may need to be changed if it is interfering with natural lubrication.
- Medications that increase blood flow or relax muscles can be helpful in some situations.
- Stool softeners can relieve dyspareunia caused by hemorrhoids.

Alternatives

Desensitization training can teach vaginal relaxation exercises to decrease pain during intercourse.

Home remedies

The use of a vaginal lubricant, even temporarily, can often relieve dyspareunia. Kegal or pelvic–floor exercises also can decrease dyspareunia.

Prognosis

With treatment dyspareunia can usually be overcome, allowing for satisfying sexual relationships. However, treatment can take several months, particularly for survivors of violent **trauma** such as rape. Persistent dyspareunia can cause women to lose all interest in sex.

Prevention

Methods for preventing dyspareunia include:

- communicating with one's partner about what is sexually pleasurable or painful
- prolonging foreplay to stimulate arousal and lubrication
- using a water- or silicone-based lubricant
- avoiding scented bath products such as shower gel and body washes, which can irritate the genitals and interfere with natural lubrication
- avoiding douching
- waiting at least six weeks after childbirth before resuming intercourse
- changing sexual positions; for example a woman may be better able to control penetration if she is on top

A false-color gamma scan of a human stomach with dyspepsia, or indigestion, during tests to study its rate of emptying. *(Custom Medical Stock Photo, Inc.)*

Dyspepsia

Definition

Dyspepsia can be defined as painful, difficult, or disturbed digestion, which may be accompanied by symptoms such as **nausea and vomiting**, **heartburn**, bloating, and stomach discomfort.

Causes and symptoms

The digestive problems may have an identifiable cause, such as bacterial or viral infection, peptic ulcer, gallbladder, or **liver disease**. The bacteria *Helicobacter pylori* is often found in those individuals suffering from duodenal or gastric **ulcers**. Investigation of recurrent **indigestion** should rule out these possible causes.

Often, there is no organic cause for the problem, in which case dyspepsia is classified as functional or nonulcer dyspepsia. There is evidence that functional dyspepsia may be related to abnormal motility of the upper gastrointestinal tract (a state known as dysmotility in which the esophagus, stomach, and upper intestine behave abnormally). These patients may respond to a group of drugs called prokinate agents. A review of eating habits (e.g., chewing with the mouth open, gulping food, or talking while chewing) may reveal a tendency to swallow air. This may contribute to feeling bloated, or to excessive belching. **Smoking**, **caffeine**, alcohol, or carbonated beverages may contribute to the discomfort. When there is sensitivity or allergy to certain food substances, eating those foods may cause gastrointestinal distress. Some medications are associated with indigestion. Stomach problems may also be a response to **stress** or emotional unrest.

Diagnosis

A **physical examination** by a health care professional may reveal mid-abdominal **pain**. A **rectal examination** may be done to rule out bleeding. If blood is found on rectal exam, laboratory studies, including a blood count may be ordered. **Endoscopy** and barium studies may be used to rule out underlying gastrointestinal disease. Upper gastrointestinal x-ray studies using barium may allow for visualization of abnormalities. Endoscopy permits collection of tissue and culture specimens which may be used to further confirm a diagnosis.

Treatment

The treatment of dyspepsia is based on assessment of symptoms and suspected causative factors. Clinical evaluation is aimed at distinguishing those patients who require immediate diagnostic work-ups from

WWW.BOOKBAZ.IR

KEY TERMS

Anemia—Diagnosed through laboratory study of the blood, a deficiency in hemoglobin or red blood cells, often associated with paleness or loss of energy.

Endoscopy—A diagnostic procedure using a lighted instrument to examine a body cavity or internal organ. Endoscopy permits collection of tissue and culture specimens.

those who can safely benefit from more conservative initial treatment. Some of the latter may require only reassurance, dietary modifications, or antacid use. Medications to block production of stomach acids, prokinate agents, or antibiotic treatment may be considered. Further diagnostic investigation is indicated if there is severe abdominal pain, pain radiating to the back, unexplained weight loss, difficulty swallowing, a palpable mass, or anemia. Additional work-up is also indicated if a patient does not respond to prescribed medications.

Prognosis

Statistics show an average of 20% of patients with dyspepsia have duodenalor gastric ulcer disease, 20% have **irritable bowel syndrome**, fewer than 1% of patients had cancer, and the range for functional, or non-ulcer dyspepsia (**gastritis** or superficial erosions), was from 5–40%.

Kathleen D. Wright, RN

Dysphasia

Definition

Dysphasia is a language disorder in which there is a partial or complete impairment of the ability to communicate resulting from brain injury or degeneration. Because dysphasia is sometimes confused with the similar (but unrelated) medical word dysphagia (a problem with swallowing), the term **aphasia** is often used interchangeably with dysphasia. Conversely, aphasia is sometimes referred to as the "complete" inability to express oneself with verbal and written communications and the inability to comprehend such spoken and written means of communications. Further, dysphasia often denotes the "partial" inability to communicate in these ways—both resulting from an injury to, or degeneration of, the brain. Various amounts of disability can occur depending on the severity of the damage and to the portion of the brain affected. Dysphasia is derived from "dys" meaning difficult and "phasis" meaning speech. Aphasia is derived from "aphaatos," which means speechless.

Demographics

The acquired speech disorder called dysphasia can occur in any human. Men and women are affected equally from the condition. Because any human can be injured because of a blow or other such sudden impact to the brain or by degeneration of the brain (such as through a **stroke** or a tumor), dysphasia can occur in any person. However, people more at risk for dysphasia are those who are more likely to be involved in head injuries. These groups of people include males between the ages of 15 and 24 years of age. They are at increased risk because of their lifestyle, which frequently involves high-risk activities such as sports. In addition, young children and the elderly—those over the age of 75 years of age—are also at elevated risk for dysphasia because of their susceptibility to head injuries, such as from accidental falls. In addition, infants are sometimes shook violently, which can lead to brain **trauma** and, consequently, dysphasia.

Description

Approximately one million Americans have one of the various forms of dysphasia, and an additional 80,000 new cases occur annually, as of statistics from 2007. By 2020, the number of current cases is estimated to increase to two million Americans and the number of annual new cases in the United States is projected to increase to 180,000, according to the National Aphasia Association. The term "dysphasia" is more frequently used by European health professionals, whereas in North American the term, "aphasia" is more commonly preferred. These two terms, however, can be and are used interchangeably.

They both refer to the full or partial loss of verbal communication skills due to damage or degeneration of the brain's language centers. Developmental dysphasia is considered to be a learning disability, but will not be the focus of this article.

Verbal communication is derived from several regions located in the language-dominant hemisphere of the brain. These include the adjacent inferior parietal lobe, the inferolateral lobe, and the posterosuperior temporal lobe, as well as the subcortical connection between these areas. Disease, direct trauma, lesion, or infarction involving one or more of these regions can disrupt or prevent proper language function. Dysphasia does not necessarily prevent proper cognitive function, so the patient can think and feel with perfect clarity. This can be extremely frustrating for the patient, as they cannot express these thoughts and feelings to others.

Dysphasia can occur in a variety of forms, depending on how the communicative disruption manifests. Classically, dysphasia can affect one or more of the basic language functions: comprehension (understanding spoken language), naming (identifying items with words), repetition (repeating words or phrases), and speech. Although there are several subtypes of dysphasias, they most commonly manifest in one of three syndromes: expressive dysphasia, receptive dysphasia, or global dysphasia.

Expressive dysphasia

Expressive dysphasia, also known as motor dysphasia, produces a conscious and recognizable disruption of a patient's speech production and language output. This includes the impairment of speech initiation, proper grammatical sequencing, and proper word forming and articulation. Although patients can perfectly understand what is said to them, they have great difficulty communicating their thoughts. They often express themselves with disjointed words and sentences. The problem is called agrammatism, which means the inability to speak in a grammatically correct manner. In the problem, the patient omit many words within a sentence so that its meaning becomes disjointed and incomprehensible at times. In less severe cases, the sentence structure may become mixed up. For instance, the sentence "The tree is green." may become "The green is tree."

BROCA'S DYSPHASIA. Broca's dysphasia is the most common type of expressive dysphasia. It is caused by damage to the lower area of the premotor cortex, located just in front of the primary motor cortex. This region is most commonly referred to as the Broca's area. Speech for patients suffering from Broca's dysphasia may be completely impossible. Others may be able to form single words or full sentences, but only through great effort. "Telegraphing," the omission of articles and conjunctions, may also be exhibited.

TRANSCORTICAL DYSPHASIA. Also known as **isolation** syndrome, transcortical dysphasia is caused by damage to the language-dominant brain that separates all or parts of the central region from the rest of the brain. There are three sub-classes of transcortical dysphasia, which define the impairments to a patient's ability to repeat words, sentences, and phrases: transcortical motor dysphasia, transcortical sensory dysphasia, and mixed transcortical dysphasia. Additional impairments may occur depending on the extent and location of the damage.

Receptive dysphasia

Receptive dysphasia, also known as sensory dysphasia, impairs the patient's comprehension and meaning of language. Unlike expressive dysphasia, the patient can speak fluently and articulately, but will utilize meaningless words, nonsensical grammar, and unnecessary phrases to the point of becoming incomprehensible. However, they will be completely unaware of their mistakes. Additionally, the patient will find it difficult to comprehend spoken language and/or word-object relation.

WERNICKE'S DYSPHASIA. Also known as semantic dysphasia, Wernicke's dysphasia is the most common of the receptive dysphasia. It is caused by damage to the Wernicke's area, located in the posterior superior temporal lobe of the language-dominant hemisphere. Although the patient can speak clearly and at length, many of their words, phases, and sentences will be nonsensical in nature. Additionally, they will experience difficulty in understanding spoken language, if not suffer a complete lack of comprehension. Semantic distinctions between words may become mixed up and jumbled, furthering confusion.

ANOMIC DYSPHASIA. Anomic dysphasia, also referred to as amnesic dysphasia, is caused by damage to the temporal parietal area and/or the angular gyrus region. Although very similar to Wernicke's dysphasia, anomic dysphasia is distinguished by its disruption of a patient's word-retrieval skills. They will be unable to correctly name people or objects, causing them to pause or substitute generalized words (like "thing"). Otherwise, the patient will exhibit few, if any, language impairments.

WWW.BOOKBAZ.IR

CONDUCTION DYSPHASIA. Also known as associative dysphasia, conduction dysphasia is a relatively uncommon disease (representing only 10% of the cases). Damage to the upper temporal lobe, lower parietal, or connection between the Wernicke's and Broca's areas can result in the inability to repeat words, phrases, or sentences. The patient may also suffer the inability to describe people or objects in the proper terms.

Global dysphasia

Global dysphasia, the third most common form of dysphasia, results from damage to both the anterior and posterior regions of the language-dominant hemisphere. In global dysphasia, all of the patient's language skills are disrupted, along with the ability to comprehend language; however, some may be disrupted more severely than others. In global dysphasia, the symptoms of both expressive dysphasia and receptive dysphasia occurs, and in a severe form.

Causes and symptoms

As of the early 2010s, over one million people in the United States suffer a permanent type of dysphasia. Although dysphasia may manifest in several ways, the common cause for its onset is damage or trauma to the brain. Stroke, in particular, is the most common cause for dysphasia. A stroke is caused from a blockage or rupture of a blood vessel within the brain. This problem causes blood flow to be reduced or cut off to brain cells, which then die or are damaged. Of the half million stroke victims reported annually in the United States, approximately 100,000 will have some form of dysphasia. Infection, direct trauma, various injuries, **transient ischemic attack** (TIA), brain tumors, and degeneration (such as **dementia**) can also instigate the onset of dysphasia.

Symptoms of dysphasia will quickly manifest after damage to the brain has occurred, and will present in accordance to the particular type of dysphasia suffered. Due to the proximity to areas of the brain that control motor function, expressive dysphasias can be accompanied by noticeable motor impairment. The majority of symptoms will be language related, including:

- Difficulty remembering words
- Difficulty naming objects and/or people
- Difficulty speaking in complete and/or meaningful sentences
- Difficulty speaking in any fashion
- Using unrecognizable words
- Difficulty reading or writing
- Difficulty expressing thoughts and feelings
- Difficulty understanding spoken language
- Using incorrect or jumbled words
- Using words in the wrong order

These symptoms may vary depending on the severity of the affliction, along with part of the brain that has been damaged. Some people with dysphasia may comprehend what other people say but have difficulty responding to such words or finding the correct words to say. Others may be able to understand the written word, but cannot speak them out loud.

Diagnosis

Dysphasia is frequently diagnosed while the patient is being treated for injury to the brain, be it from trauma or disease. The health professional, typically a neurologist, will conduct standard cognitive tests, including tests to determine whether the patient's language centers have been affected. If the patient exhibits signs of difficulty communicating, they will often be referred to a speech-language pathologist. In turn, the pathologist will conduct a comprehensive examination of the patient's ability language and comprehension skills. This examination may begin with evaluating the patient's ability to repeat words and phrases, recognize and describe objects, and comprehend what is said to them. More extensive and standardized language-based tests may be required, including the Porch Index of Speech Ability and the Boston Diagnostic Aphasia Examination. Based on the result of the examinations, the health professional will be able to determine the type of dysphasia inflicting the patient. More extensive damage may require the use of computed tomography (CT) or **magnetic resonance imaging** (MRI) for an effective diagnosis.

Treatment

A specific treatment is not available, due to the various forms of the condition, and its severity. Initially it is necessary to treat and stabilize the injury underlying the development of the patient's dysphasia. In some cases, such as with damage caused by TIA, a full recovery can be expedient and takes only a few days. Unfortunately, most dysphasias can take months, if not years, to recover from the problem. Even after prolonged therapy, many patients never achieve a full recovery. Efficacy of treatment greatly depends on the promptness with which it begins. **Speech therapy** is effective at promoting a full or partial recovery. For this reason, many medical facilities have speech-language pathologists on staff to begin the initial treatment process as quickly as possible.

KEY TERMS

Transient ischemic attack—Also known as a mini-stroke, a transient ischemic attack is caused by a temporary interruption of blood flow in an area of the brain. Unlike in a true stroke, normal brain function will return with 24 hours.

There is not a medical or surgical cure for dysphasia. Treatment, instead, relies strongly upon the use of various speech therapies. Much like **physical therapy** strengthens muscles and bones back to normalcy, speech therapy allow the patient to regain language function, as well as rebuild their communications skills. Treatment is typically conducted with a trained speech therapist. However, group sessions are common and allow the patient to practice their language skills in a non-threatening environment with others sharing their disability. Although much of therapeutic work is conducted by a speech therapist, friends and family also play a vital role in the patient's recovery. They can help the patient continually practice and exercise language skills while outside the therapeutic setting. Many times, family members are included on therapy sessions to teach them how to communicate with and understand the patient.

There are several treatments available, which utilize the patient's remaining language abilities to rebuild and compensate for those that were lost. These include out-put focused therapy (stimulation-response), psycholinguistic therapy (cognitive), cognitive neurorehabilitation, and combinations thereof. Although these treatments approach aphasia differently, they all share a common thread by identifying the specific communication deficits and then targeting them with various modalities (computer-aided therapy, picture cards, reading and writing exercises, speech practice, etc.). These techniques stimulate the various parts of the brain associated with language, memory, and understanding, and allow it to heal. Therapies may frequently use computers to assist the patient in regaining the ability to communicate. In addition, patients who cannot recover from dysphasia can use communication devices, such as computers, to convey their thoughts back and forth between friends and family.

Medical researchers are also experimenting with and testing various drugs that may be used in the future to treat dysphasia, either in combination with speech therapy or not.

Prognosis

About half of patients will have transient dysphasia, in which the symptoms fade completely after only a few days. However, a patient's prognosis will greatly depend on several factors, such as the cause and the location and extent of the underlying damage. Additional factors of importance are the patient's age, general health, and mental health and motivation. Children under the age of eight years usually regain their language skills even after serious damage to the brain. Handedness may also be an indicator for recovery, as left-handed individuals have language centers located in both hemispheres of the brain (not just the left). As such, left-handed patients have access to language skills from either side of the brain, which can expedite their recovery. Even with speech therapy, dysphasia may take several years to overcome. Indeed, some patients will never regain their pre-trauma skill level of communication and speech. In such cases, alternative methods of communications may be necessary, such as sign language.

Prevention

Dysphasia can be prevented by avoiding the causes of brain injury and stroke, such as high blood pressure. In particular, eating a healthy diet and not **smoking** to maintain proper blood pressure will help prevent damaging strokes. Although it is impossible to predict head trauma, the use of head protection while participating in dangerous sports or activities can reduce the risk of serious brain damage.

E

E-cigarettes

Definition

E-cigarettes, more properly known as electronic cigarettes, are personal electronic devices that heat a nicotine solution with a battery-powered electric coil called an atomizer. When the solution is heated, an aerosol resembling smoke is released, which the user can inhale as if he or she were puffing on a cigarette. E-cigarettes are also called e-cigs, personal vaporizers (PVs), and electronic nicotine delivery systems (ENDS). The use of an e-cigarette is popularly termed vaping. Although e-cigarettes do provide users with a dose of nicotine (whose strength varies considerably from manufacturer to manufacturer), they are considered by many to be safer than cigarettes because they do not release the tar and other harmful compounds given off by burning tobacco.

Description

Since their introduction to the worldwide market in 2004, e-cigarettes have undergone considerable evolution. Early models were designed to resemble conventional cigarettes or cigars; they are called cig-a-likes. Some are designed to look like ballpoint pens and are popularly known as pen-styles. The third type of e-cigarette in use as of 2014 are advanced mods, called mods for short, which may resemble a box or flashlight; however, mods can be found in all shapes and sizes with their common element being a large removable and rechargeable battery. While most e-cigarettes use solutions containing nicotine, a significant minority of PVs use nicotine-free solutions that release vapors flavored to resemble coffee, fruits, vanilla, or alcoholic beverages like piña colada. Some users prefer to call these devices e-hookahs or vape pens to distinguish them from PVs that use nicotine-based solutions. In fact, the emergence of nicotine-free PVs has intensified the controversy over the possible health consequences of e-cigarettes.

Some observers trace the origin of e-cigarettes back to the mid-1960s, when a so-called smokeless non-tobacco cigarette was patented. After 1965, some inventors were experimenting with a charcoal-based vaporizer used to heat a nicotine solution, but the devices were clumsy as well as expensive to use. Ironically, it was the invention of cell phones that led to the development of contemporary e-cigarettes. The need to shrink the size of cell phones and invent longer-lasting batteries to power them made it possible to fit a battery and electric coil, along with a cartridge containing a nicotine solution, inside a cylinder the size and shape of a standard tobacco cigarette.

The invention of the first e-cigarette is usually credited to Hon Lik, a Chinese pharmacist, who first sold the device as a **smoking** cessation aid in 2004. From China (where most e-cigarettes are still manufactured as of 2014), e-cigarettes were exported to Vietnam, where they were discovered by a Belgian entrepreneur, J. Andries Verleur. Verleur had the Chinese manufacturers improve the design of Hon Lik's original product; he then formed a company and began selling e-cigarettes worldwide in 2009. While the devices were slow to find acceptance at first, they have grown explosively in only five years. As of 2014, there are at least 466 brands of e-cigarettes on the market, up from 288 in 2012. The number of e-cigarettes sold in North America expanded from 50,000 in 2008 to 3.5 million in 2012. There are an estimated 2 million users of PVs in the United Kingdom alone as of 2014. A survey conducted by the Centers for Disease Control and Prevention (CDC) found that 1.78 million American adolescents had tried e-cigarettes in 2012, up from half that number just a year earlier; and

Close up of a woman inhaling from an electronic cigarette. *(© scyther5/Shutterstock.com)*

that 10% of those teenage users had never tried conventional cigarettes or other tobacco products.

The cost of vaping in comparison to the cost of cigarettes is a point that many vapers make to justify switching to e-cigarettes. With a pack of cigarettes costing as much as $8 or even $9 in parts of the United States, e-cigarettes look like a way to satisfy a craving for nicotine at a lower cost. E-cigarettes, however, are not cheap: typical starter kits begin at $50 on up to several hundred dollars. One popular kit costs about $80; it includes a battery charger that also serves as a storage container, two batteries, and five nicotine cartridges, each good for about 150 puffs. The kit's total cost is about the same as 8 to 16 packs of cigarettes.

Purpose

Personal satisfaction

The basic purpose of an e-cigarette is to deliver a pleasurable vapor, usually though not always containing nicotine, to the user by inhalation. Most e-cigarettes contain the following components:

- The mouthpiece: also known as the cartridge, the mouthpiece contains a heating coil that vaporizes the e-liquid when the user sucks on the mouthpiece. Other names for the larger cartridges in newer e-cigarettes are cartomizer or tank.
- The atomizer. The atomizer is the heating device (usually an electric coil) that vaporizes the e-liquid. It requires replacement every 3–6 months.
- The battery: The battery is the power source of an e-cigarette. It is the largest component of most e-cigarettes and takes up most of the space inside the external cylinder. Most new models of e-cigarettes contain rechargeable lithium-ion batteries. Early e-cigarettes had a switch that turned the battery on and off, while an LED at the other end of the e-cigarette glowed when the user inhaled. Newer e-cigarette batteries contain airflow sensors that activate the battery when the user inhales through the mouthpiece. Advanced mods may allow for variable power output or a wide variety of battery and atomizer configurations.
- The e-liquid: The e-liquid, also called juice, may or may not contain nicotine. In most cases it is a mixture of propylene glycol (which is the source of the vapor that appears when the e-cigarette is used); vegetable glycerine; and flavorings. The cartridge can either be replaced or refilled by the user when the liquid is gone. E-liquid is also sold in bottles or in kits that allow users to make their own juice and modify or intensify its flavor.

Smoking cessation

One of the major controversies about e-cigarettes is whether they can serve the purpose of smoking cessation. As noted above, the pharmacist who invented the first e-cigarette marketed it as a smoking cessation device. As of 2014, medical researchers are sharply divided as to whether e-cigarettes are useful in weaning users from conventional tobacco products, or whether they are gateway products that will create a new generation of nicotine addicts. The fact that many teenagers as well as adults who have never smoked tobacco are using e-cigarettes is grounds for worry in the minds of some researchers. At present, the medical and scientific communities disagree strongly about the merits of e-cigarettes as aids to smoking cessation. Most researchers acknowledge that further research is necessary. One of the complications to doing such research, however, is the lack of standardization in regard to the nicotine content, flavoring agents, and other components of e-cigarettes. The sheer variety of models and flavors would add to the difficulty of setting up a controlled clinical trial.

The social dimension of smoking is another cause for concern among health researchers about e-cigarettes. It has been known for years that one of the reasons that smoking is a difficult habit to break is the ritual behaviors associated with it. For many shy people, the ritual of lighting up, sharing cigarettes with others, and smoking as part of a convivial get-together helped to ease the way into social situations. Smoking was also associated with

WWW.BOOKBAZ.IR

glamor and sophistication up through the 1970s, when it became increasingly stigmatized as a cause not only of lung disease in smokers themselves but also a danger to nonsmokers through secondhand smoke.

Some researchers fear that the increasing use of high-end e-cigarettes, particularly the expensive customized models, will reverse the stigma presently associated with smoking and make the habit socially acceptable or even prestigious again. This concern is based partly on the fact that the vapor of an e-cigarette is much less noticeable (thus much less annoying) to others nearby than the smoke of a conventional cigarette or cigar; and partly on the emergence of a distinct subculture based on vaping. Some members of the so-called vaping community are attracted to the lifestyle of vaping, others consider it a hobby, while most are attracted to it as a safer alternative to smoking. Members of the vaping subculture spend thousands of dollars on vaping devices, hold gatherings around the United States, and have formed a National Vapers Club, which raises funds for research about e-cigarettes.

KEY TERMS

Atomizer—The battery-powered electric coil inside an e-cigarette that vaporizes the e-liquid. It contains a wick that draws in the e-liquid for vaporization.

E-hookah—An informal term for a personal vaporizer that does not use a fluid containing nicotine. E-hookahs are also called hookah pens or vape pens.

E-liquid—The solution contained in an e-cigarette that is vaporized when the device is used. Also called juice, it typically contains propylene glycol, vegetable glycerine, flavorings of various types, and (in most cases) nicotine.

Vaping—An informal term for the use of e-cigarettes.

Risks

The risks associated with e-cigarettes can be summarized as follows:

- The social risk of undoing 50 years of successful anti-smoking campaigns and health regulations, increasing the total number of people addicted to nicotine worldwide.
- Increasing the popularity of nicotine-based products among teenagers, particularly by the creation of sweet or candy-like e-cigarette flavors that are attractive to youngsters. In addition, because the sale of e-cigarettes in the United States is not regulated in the same way as tobacco products as of 2014, teenagers can easily purchase them online.
- The possibility that the vapor from e-cigarettes poses some health risks to others, even though the nicotine content of the vapor is considerably lower than that of conventional cigarettes and contains no tar. The vapor does, however, contain heavy metals, some by-products of nicotine, and ultrafine particles, but whether these pose health hazards on the level of secondhand tobacco smoke is far from certain.
- The unknown risks of long-term inhalation of propylene glycol (PEG), the organic molecule that appears as visible vapor when an e-cigarette is used. Although PEG is considered safe for use in foods and is used in theatrical performances to create fog or mist onstage, no one knows whether years of inhaling it in an e-cigarette is safe.
- Quality control issues with the flavorings used in e-liquids. Some cartridges have been found to be contaminated, and there are no industry standards for the flavorings used; some ingredients may be potentially toxic. In addition, some flavoring agents may be carcinogenic.
- A significant increase in the number of child poisonings reported to the CDC involving e-cigarette e-liquid refills containing nicotine. Nicotine is poisonous in even small amounts, and can cause vomiting, seizures, and death. The CDC reported that calls to poison control centers concerning poisoning from e-cigarette cartridges rose from an average of one per month in 2010 to 215 per month by early 2014. Children or adults can take in nicotine from e-liquids in one of three ways: inhalation, swallowing, or absorption through the skin or eyes.

Unsurprisingly, the exponential increase in the popularity of e-cigarettes in just a few years has led to calls for government regulation. In August 2014, the World Health Organization released a report on ENDS urging member countries to 1) restrict the use of e-cigarettes indoors; 2) ban candy-like, fruit-based, or alcoholic beverage-based flavors; and 3) limit sales to persons over the age of 18. Most researchers note, however, that any such restrictions will take years to implement.

Although the U.S. Food and Drug Administration (FDA) originally attempted to regulate e-cigarettes as "drug delivery devices" under the Food, Drug, and Cosmetic Act of 1938, this classification was overruled in 2010 by a federal district court. As of late 2014, the FDA has not yet issued a final rule concerning the reclassification or regulation of e-cigarettes. The agency presently states that "only e-cigarettes that are marketed for therapeutic purposes are currently regulated by the FDA Center for Drug Evaluation and Research (CDER)." The FDA's Center for Tobacco Products currently regulates only cigarettes, cigarette tobacco, roll-your-own cigarettes, and smokeless tobacco. While most analysts expect the FDA to restrict the sale of e-cigarettes over the Internet, no one yet knows what other restrictions the agency may impose.

There is little uniformity either worldwide or in the United States regarding restrictions on e-cigarettes as of 2014. Some countries, including Singapore and the United Arab Emirates, ban all e-cigarettes as illegal, while some European countries ban only those containing nicotine, and others restrict only the indoor use of e-cigarettes. In the United States, different states have taken different approaches to e-cigarettes, with most states banning their use in enclosed spaces like bars and restaurants, and nine states banning their sale to minors.

Ear exam with an otoscope

Definition

An otoscope is a hand-held instrument with a tiny light and a cone-shaped attachment called an ear speculum, which is used to examine the ear canal. An ear examination is a normal part of most physical examinations by a doctor or nurse. It is also done when an ear infection or other type of ear problem is suspected.

Purpose

An otoscope is used to look into the ear canal to see the ear drum. Redness or fluid in the eardrum can indicate an ear infection. Some otoscopes can deliver a small puff of air to the eardrum to see if the eardrum will vibrate (which is normal). This type of ear examination with an otoscope can also detect a build up of wax in the ear canal, or a rupture or puncture of the eardrum.

Precautions

No special precautions are required. However, if an ear infection is present, an ear examination may cause some discomfort or **pain**.

Description

An ear examination with an otoscope is usually done by a doctor or a nurse as part of a complete **physical examination**. The ears may also be examined if an ear infection is suspected due to **fever**, ear pain, or **hearing loss**. The patient will often be asked to tip the head slightly toward the shoulder so the ear to be examined is pointing up. The doctor or nurse may hold the ear lobe as the speculum is inserted into the ear, and may adjust the position of the otoscope to get a better view of the ear canal and eardrum. Both ears are usually examined, even if there seems to be a problem with just one ear.

Preparation

No special preparation is required prior to an ear examination with an otoscope. The ear speculum, which is inserted into the ear, is cleaned and sanitized before it is used. The speculums come in various sizes, and the doctor or nurse will select the size that will be most comfortable for the patient's ear.

Aftercare

If an ear infection is diagnosed, the patient may require treatment with **antibiotics**. If there is a buildup of wax in the ear canal, it might be rinsed or scraped out.

Risks

This type of ear examination is simple and generally harmless. Caution should always be used any time an object is inserted into the ear. This process could irritate an infected external ear canal and could rupture an eardrum if performed improperly or if the patient moves.

Results

The ear canal is normally skin-colored and is covered with tiny hairs. It is normal for the ear canal to have some yellowish-brown earwax. The eardrum is typically thin, shiny, and pearly-white to light gray in color. The tiny bones in the middle ear can be seen pushing on the eardrum membrane like tent poles. The

KEY TERMS

Ear speculum—A cone- or funnel-shaped attachment for an otoscope that is inserted into the ear canal to examine the eardrum.

Otoscope—A hand-held instrument with a tiny light and a funnel-shaped attachment called an ear speculum, which is used to examine the ear canal and eardrum.

light from the otoscope will reflect off of the surface of the ear drum.

An ear infection will cause the eardrum to look red and swollen. In cases where the eardrum has ruptured, there may be fluid draining from the middle ear. A doctor may also see scarring, retraction of the eardrum, or bulging of the eardrum.

Altha Roberts Edgren

Ear, nose, and throat surgery

Definition

Ear, nose, and throat surgery is the surgical treatment of diseases, injuries, or deformations of the ears, nose, throat, head, and neck areas.

Purpose

The purpose of surgery on the ears, nose, throat, head, and neck is to treat an abnormality, such as a defect or disease, in these anatomical areas. An anatomical deformity is a change that usually occurs during embryological development, leaving the affected person with the apparent defect. A disease in this area usually develops later in life, such as **head and neck cancer**. Additionally, the specialty known as otorhinolaryngology (ears [*oto*]; nose [*rhino*]; and throat [*laryn*], referring to the larynx or throat) also includes surgical intervention for diseases in the head and neck regions. Most ear, nose, and throat (ENT) surgeons in the United States are referred to as otolaryngologists and the specialty as otolaryngology. **Ear surgery** is usually performed to correct specific causes of **hearing loss**. Nose surgery can include different types of procedures necessary to treat sinus problems, like sinus surgery. Throat surgery can include complicated procedures such as cancer of the larynx resulting in a **laryngectomy**, or more simple procedures such as surgical removal of the adenoids, known as an **adenoidectomy**, or tonsils, known as a **tonsillectomy**. Head and neck surgery may be necessary to remove a tumor or reconstruct an area after disfigurement from **trauma** or injury.

Demographics

Ear, nose, and throat surgery comprises many different types of surgical procedures and spans over all age groups regardless of gender or ethnicity. Pediatric otolaryngology, a subspecialty, is the branch that treats ENT problems in infants and children.

Description

ENT surgery is the oldest surgical specialty in the United States, and it is one of the most elaborate fields of surgical specialty services, using advanced technology and a broad range of procedures that also includes major **reconstructive surgery** to correct deformity or injury. **Cosmetic surgery** can include chin augmentation, **hair transplantation**, and surgical procedures to improve wrinkles in the face and contours of the nose and ears.

Typically, ear surgery corrects defects causing hearing loss or impairment. Such procedures include **stapedectomy**, the removal of all or part of a bone in the middle ear called the stapes; tympanoplasty, the reconstruction of the ear drum; and **cochlear implants**, the implantation of a device that stimulates nerve endings within the inner portion of the ear to enable hearing. Surgery of the ear also includes myringotomy, or insertion of ear tubes to drain fluid in persons with chronic ear infections.

WWW.BOOKBAZ.IR

Common surgical procedures of the throat include removal of tonsils (tonsillectomy) or adenoids (adenoidectomy). The tonsils, found on either side and in back of the throat, and adenoids, which are higher up the throat behind the nose, are masses of lymph tissue that play an active role in the body's defenses to fight infection. The tonsils and adenoids can get chronically infected, in which case surgical removal is usually indicated to relieve breathing problems and infection recurrence. Furthermore, chronic inflammation of the adenoids can cause repeated middle ear infections that can ultimately impair hearing.

Surgery of the nose can include procedures that treat sinus diseases. Advanced endoscopic surgery for sinus and nasal disorders can eliminate the need for external incisions and greater surgical precision. Other common surgical procedures include correction of a deviated nasal septum (**septoplasty**) and elimination of chronic nasal obstruction (congestion).

Surgery of the neck region can commonly include **tracheotomy**, a surgical procedure in which an opening is made in the trachea or windpipe. Tracheotomy is indicated for a person who is unable to deliver enough oxygen to the lungs. ENT surgeons also perform complicated surgical procedures for the treatment of malignant head and neck cancers. In addition to **tumor removal**, when indicated, ENT surgeons may perform an operation called **radical neck dissection**, during which the ENT will remove cancer that has spread via lymphatic vessels to regional neck lymph nodes. Neck dissection is also useful since specimens can be removed for pathological examination, which can provide important information concerning metastasis and can direct the treatment plan (e.g., **radiation therapy** and/or **chemotherapy** may be recommended for aggressive cancers). ENT surgeons also treat sleep-related disorders such as **sleep apnea** and excessive **snoring**; a procedure called laser-assisted uvulopalatoplasty (LAUP) will remove tissue to allow for unobstructed airflow.

Other ENT procedures include surgical reconstruction of ear deformities (otoplasty), special surgery for diseases in the inner ear, and skull-based surgeries (neuro-otology). ENT surgeons can surgically treat abnormalities near the eye, perform oral surgery for treatment of dental and jaw injury, and remove **skin cancer** within the head and neck region. ENT surgeons also perform special surgical techniques that can preserve nerve and blood vessel function (**microsurgery**) and reconstruction of bone and soft tissue.

Diagnosis

A careful history and **physical examination** of the ears, nose, throat, head, and neck is a standard approach during initial consultation. Different instruments with light sources, like an otoscope for ear examinations, enable ENT surgeons to quickly visualize the ears, nose, and throat. Visualization of these areas can reveal the severity of the disease or deformity. The head and neck area is inspected and the neck and throat area is typically felt with the surgeon's hands, a technique known as palpation. Special technological advancements have enabled ENT surgeons to further visualize deep internal anatomical structures. Nasal **endoscopy**, for example, allows visualization of the upper airway to detect anatomical problems related to sinuses; videostroboscopy can be used to visualize the vocal cords; and triple endoscopy (**laryngoscopy**, esophagoscopy, and **bronchoscopy**) can diagnose and stage head and neck cancers.

Preparation

Preparation before surgery is fairly standardized and includes blood work-up and instructions to have nothing to eat or drink after midnight of the night before the procedure.

The procedure is usually performed in a hospital with an ENT department, an ambulatory surgery center, or a specially equipped doctor's office. The ENT surgeon receives one year of general surgical training and five years of training in the disease and surgery of the ears, nose, throat, head, and neck. Most surgeons are board certified. Some ENT surgeons obtain a further one to two years of advanced training in one of the seven areas of subspecialty that includes otology/neuro-otology, pediatric otolaryngology, head and neck area, facial plastic and reconstructive surgery, rhinology (treatment of diseases of the sinuses and nose), laryngology (treatment of throat diseases), and allergy. The department typically provides other professional clinical services during diagnosis and treatment, such as speech-language pathologists and hearing specialists. Larger medical centers may also have one or two medical researchers on staff.

Aftercare

The aftercare for ENT surgery depends on the procedure and state of the health of the patient. The aftercare for a patient who is 60 years old with head/neck cancer is more extensive than that for a

KEY TERMS

Cancer staging—A surgical procedure to remove a lymph node and examine the cells for cancer. It determines the extent of the cancer and how far it has spread.

Metastasis—The spread of cancer cells from a cancerous growth or tumor into other organs of the body.

tonsillectomy performed in a young adolescent or child. Aftercare for adolescents or children undergoing minor procedures such as myringotomy is often minimal, and the patient usually goes home a few hours after the procedure. Generally, aftercare should be directed toward wound care and knowledge gained from the surgeon specifically detailing the expected length of average convalescence. Wound care, such as cleansing and dressing changes, and postoperative follow-up with the ENT surgeon is essential. Medications for **pain** may be prescribed. Patients may stay in the hospital for 8–10 hours for the effects of **anesthesia** to subside for same-day surgical procedures like a tonsillectomy, or they may be admitted for a few days for more complicated procedures, such as those related to cancer treatment. Aftercare and convalescence may take longer for complicated procedures such as advanced cancer, tumors, or temporal bone surgery for nerve disorders that can affect balance.

Risks

The risk of ENT surgery depends on the procedure and the health status of the patient. Some procedures do not have much risk, while complications for other procedures can carry considerable risk. For example, a complicated operation such as neck dissection could result in loss of ear sensation, since the nerve that provides the feeling of sensation is commonly severed during the procedure.

Results

There will be a cure or an improvement of the primary disease. Ear surgery should help individuals hear well. Throat surgery can help remove chronically inflamed tonsils, adenoids, polyps, or cancer. Nose surgery for deviated septums or nasal congestion will improve breathing problems and help a person breath more easily and effectively through the nose. Neck surgery can remove diseased tissue and prevent further spread of cancer. Surgery for sleep apnea will remove redundant tissue that blocks airways and obstructs normal airflow.

Outcome and disease progression vary for each disease state. There are no general statistics for all ENT procedures. Some procedures are generally correlated with excellent morbidity and no mortality, such as the over 90% success rate for all cases receiving tympanoplasty, while others may be associated with poor outcomes and illness, such as advanced head/neck cancer.

Alternatives

Usually, surgery is indicated when benefit from surgery is a clear-cut primary intervention or when medical or conservative treatment has failed to provide sustained symptomatic improvement. A person diagnosed with cancer may not have an alternative conservative treatment, depending on the stage of their cancer; however, a person with sinus problems may be treated conservatively with **antibiotics**, saline nasal spray wash, steroid nasal spray, and/or antihistamine spray before indication or necessity for surgery. There are many other services that the ENT surgeon uses to treat specific diseases, including audiology services for diagnostic and therapeutic purposes, like **hearing aids**, and services to treat disorders of speech and voice.

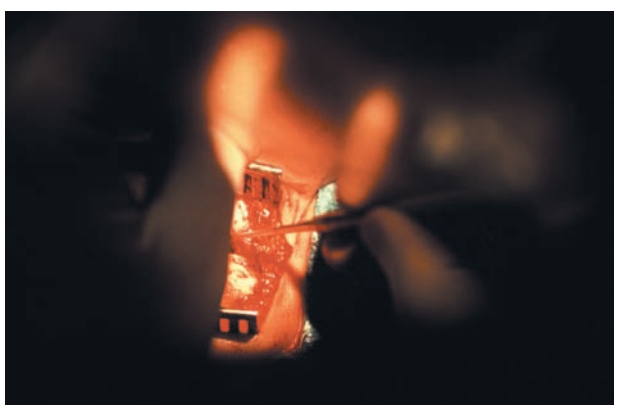
Ear surgery

Definition

Ear surgery is the treatment of diseases, injuries, or deformations of the ear by operation with instruments.



Microsurgery being performed in the inner ear. *(Hans Halberstadt/Photo Researchers, Inc.)*

Purpose

Ear surgery is performed to correct certain types of **hearing loss**, and to treat diseases of, injuries to, or deformities of the ear's auditory tube, middle ear, inner ear, and auditory and vestibular systems. Ear surgery is commonly performed to treat conductive hearing loss, persistent ear infections, unhealed perforated eardrums, congenital ear defects, and tumors.

Ear surgery is performed on children and adults. In some cases, surgery is the only treatment; in others, it is used only when more conservative medical treatment fails.

Precautions

The precautions vary, depending on the type of ear surgery under consideration. For example, **stapedectomy** (removal of parts of the middle ear and insertion of prosthesis parts) should not be performed on people with external or middle ear infection or inner ear disease. For people with complete hearing loss in the other ear, it should be performed cautiously. **Microsurgery** for the removal of a cholesteatoma (a cyst-like mass of cells in the middle ear) should not be performed on patients who are extremely ill or have other medical conditions. Tympanoplasty (any surgical procedure on the eardrum or middle ear) should not be performed on patients with chronic sinus or nasal problems or with medical problems such as poorly controlled diabetes and **heart disease**. Surgery for congenital microtia and atresia (abscense of normal bodily openings, such as the outer ear canal) should not be performed if the middle ear space is totally or almost totally absent.

Description

Most ear surgery is microsurgery, performed with an operating microscope to enable the surgeon to view the very small structures of the ear. The use of minimally invasive **laser surgery** for middle ear procedures is growing. Laser surgery reduces the amount of **trauma** due to vibration, enhances coagulation, and enables surgeons to access hard to reach places in the middle ear. Laser surgery can be performed in an office operating suite. Types of ear surgery include stapedectomy, tympanoplasty, myringotomy and ear tube surgery, ear surgery to repair a **perforated eardrum**, **cochlear implants**, and **tumor removal**.

Stapedectomy

To restore hearing loss, which is usually due to **otosclerosis**, stapedectomy is performed.

Stapedectomy is the removal of all or part of the stapes, one of the bones in the middle ear, and replacement with a tiny prosthesis. An incision is made in the middle ear, the small bones are identified, and the stapes is removed. The stainless steel wire and cellulose sponge prosthesis is inserted, blood and fluid are drained, and the wound is closed. Performed in a hospital or outpatient surgical facility under local or general anesthetic, full recovery takes about three weeks but hearing should improve immediately.

Tympanoplasty

Tympanoplasty is performed to reconstruct the eardrum after partial or total conductive hearing loss, usually caused by chronic middle ear infections, or perforations that do not heal. This is usually a same day surgery, performed under either local or general **anesthesia**. After making an incision in the ear to view the perforation, the ear drum is elevated away from the ear canal and lifted forward. If the bones of hearing (ossicular chain) are functioning, tissue is taken from the ear and grafted to the eardrum to close the perforation. A thin sheet of silastic and Gelfoam hold the graft in place. The ear is stitched together, and a sterile patch is placed on the outside of the ear canal. Tympanoplasty is successful in over 90% of all cases. The need for ossicular reconstruction (reconstruction of tiny bones of the middle ear) is sometimes known before surgery and even when identified during surgery, can usually be done while reconstructing the eardrum. If the gap between the anvil bone and the stapes is small, a small piece of bone or cartilage from the patient can be inserted; if is is large, the incus bone is removed, modelled into a prosthesis, and reinserted between the stapes and the malleus. Reconstruction could also be achieved by inserting a strut made from artificial bone. For tympanoplasty with ossicular reconstruction, the patient usually stays in the hospital overnight. The recovery period is about four weeks.

Myringotomy and ear tube surgery

Myringotomy and ear tube surgery is performed to drain ear fluid and prevent ear infections when **antibiotics** are not effective or when ear infections are chronic. The process normalizes pressure in the middle ear and decreases fluid accumulation. It is most commonly performed on infants and children, in whom ear infections are most frequent, and may be done on one or both ears. The surgeon makes a small hole in the ear drum, then uses suction to remove fluid. A small ear tube of metal or plastic is inserted into the ear drum to allow continual drainage. The tube prevents infections as long as it stays in place, which varies from six months to three years. When the tube falls out, the hole grows over. As many as 25% of children under the age of two who need ear tubes may need them again. Myringotomy and ear tube surgery is performed in a hospital, using a general anesthetic for most children and a local anesthetic for older children or adults. No anesthetic may be used for infants. The procedure usually takes about two hours. Most patients can go home the same day; children under three years of age and those with chronic diseases usually stay overnight.

Ear surgery for a perforated eardrum

Ear surgery for a perforated eardrum is only performed in rare cases where it does not heal on its own. In most cases, this is performed in a surgeon's office using a topical anesthetic. The surgeon scratches the undersurface of the eardrum, stimulating the skin to heal and the eardrum to close. A thin patch placed on the eardrum's outer surface allows the skin under the eardrum to heal.

Cochlear implants

Cochlear implants stimulate nerve ends within the inner ear, enabling deaf children to hear. The device has a microphone that remains outside the ear, a processor that selects and codes speech sounds, and a receiver/stimulator to convert the coded sounds to electric signals that stimulate the hearing nerve and are recognized by the brain as sound. During surgery, an incision is made behind and slightly above the ear. A circular hole is drilled in the bone to receive the device's internal coil. The mastoid bone leading to the middle ear is opened to receive the electrodes. The internal coil is inserted and secured, followed by the electrodes. The wound is stitched up and when it heals, an external unit comprised of a stimulator with a microphone is worn behind the ear. Performed in a hospital under general anesthesia, the operation takes about two hours and usually requires a hospital stay overnight. The patient can resume normal activities in two to three weeks.

Ear surgery for tumors

Some ear tumors can be very serious and should be removed surgically. For a tumor on the skin of the ear canal, the skin is removed surgically, the bone beneath it is drilled away and a skin graft is placed in the ear canal. If the tumor is near the eardrum, the skin of the ear canal and the eardrum are removed along with the bone surrounding the ear canal. A skin graft is placed on the bare bone. For basal cell cancers and low

KEY TERMS

Auditory—Relating to the sense of the organs of hearing.

Cholesteatoma—A cystic mass of cells in the middle ear, occurring as a congential defect or as a serious complication of a disease or traumtic condition of the ear.

Otologic—Relating to the study, diagnosis, and treatment of diseases of the ear and related structures.

grade glandular malignancies, surgical resection of the ear canal is adequate. Squamous cell carcinoma, a serious form of cancer, of the external ear canal requires radical surgery, followed by **radiation therapy**. Cholesteatoma, a benign tumor caused by an infection in a perforated eardrum that did not heal properly and can destroy the bones of hearing, is removed with microsurgery. **Mastoidectomy** is performed for **mastoiditis**, an inflammation of the middle ear, if medical therapy does not work. Petrous apicectomy is performed to drain the petrous apicitis, the bone between the middle ear and the clivis.

Ear surgery for congenital ear defects

Congenital atresia, the absence of the external ear canal, and congenital microtia, abnormal growth of the external ear, often occur together, although atresia can occur without microtia. Surgery to reconstruct the ear usually takes place when the child is four or five years old and may require several operations. A facial plastic surgeon and an ear surgeon work together, repairing the microtia first and then the atresia. During surgery, a bony opening is created over the bones of hearing. The surfaces of the bony ear canal are then relined with a skin graft from the thigh or abdomen. Tissue from behind the eardrum is used to create a new eardrum. In many cases, the middle ear will also need to be reconstructed. Surgery is performed in a hospital under general anesthesia.

Other types of ear surgery

Surgery may also be appropriate to remove multiple bony overgrowths of the ear canal or in rare cases of compromised auditory tube function, to narrow the tube.

Preparation

The preparation depends upon the type of ear surgery performed. For many procedures, blood and urine studies and hearing tests are conducted.

Aftercare

The type of aftercare depends upon the type of surgery performed. In most cases, the ear(s) should be kept dry and warm. Non-prescription drugs such as **acetaminophen** can be used for **pain**.

Risks

The type of risk depends on the type of surgery performed. Total hearing loss is rare.

Eating disorders

Definition

Eating disorders (EDs) are psychiatric disorders that have diagnostic criteria based on psychologic, behavior, and physiologic characteristics that usually result in abnormal eating patterns that have a negative effect on health.

Symptoms of eating disorders

Anorexia nervosa	Bulimia nervosa	Binge-eating disorder
Resistance to maintaining body weight at or above a minimally normal weight for age and height	Recurrent episodes of binge eating, characterized by eating an excessive amount of food within a discrete period of time and by a sense of lack of control over eating during the episode	Recurrent episodes of binge eating, characterized by eating an excessive amount of food within a discrete period of time and by a sense of lack of control over eating during the episode
Intense fear of gaining weight or becoming fat, even though underweight	Recurrent inappropriate compensatory behavior in order to prevent weight gain, such as self-induced vomiting or misuse of laxatives, diuretics, enemas, or other medications (purging); fasting; or excessive exercise	The binge-eating episodes are associated with at least 3 of the following: eating much more rapidly than normal; eating until feeling uncomfortably full; eating large amounts of food when not feeling physically hungry; eating alone because of being embarrassed by how much one is eating; feeling disgusted with oneself, depressed, or very guilty after overeating
Disturbance in the way in which one's body weight or shape is experienced, undue influence of body weight or shape on self-evaluation, or denial of the seriousness of the current low body weight	The binge eating and inappropriate compensatory behaviors both occur, on average, at least twice week for 3 months	Marked distress about the binge-eating behavior
Infrequent or absent menstrual periods (in females who have reached puberty)	Self-evaluation is unduly influenced by body shape and weight	The binge eating occurs, on average, at least 2 days a week for 6 months
		The binge eating is not associated with the regular use of inappropriate compensatory behaviors (e.g., purging, fasting, excessive exercise)

Demographics

According to the National Comorbidity Survey Replication study, reported lifetime prevalence rates for **anorexia nervosa** were 0.3% in men and 0.9% in women; for **bulimia nervosa**, 0.5% in men and 1.5% in women; and for **binge eating disorder**, 2% in men and 3.5% in women. In general, more women have eating disorders than men, and according to the National Eating Disorder Association, an estimated 10 million females in the United States have some form of eating disorder. The age at which a person develops an ED differs within conditions, with the greatest frequency of anorexia nervosa and bulimia nervosa occurring during adolescence, whereas binge eating disorder occurs well into adulthood. There are also clinical reports that show an increasing trend in EDs for middle-aged women. Longitudinal research has documented that 12% of adolescent girls aged 12 to 15 years, have experienced some form of ED. Anorexia athletica, muscle dysmorphic disorder, and orthorexia nervosa tend to be more common in men. Rumination, **pica**, and **Prader-Willi syndrome** affect men and women equally.

Anorexia nervosa begins primarily between the ages of 14 and 18 and affects mainly white girls. Bulimia usually develops slightly later, in the late teens and early twenties. Binge eating disorder is a problem of middle age and affects blacks and whites equally. Prader-Willi syndrome begins in the toddler years. Not enough is known about the more newly classified disorders—such as anorexia athletica, muscle dysmorphic disorder, and orthorexia nervosa—to determine when they are most likely to develop or which races or ethnic groups are most likely to be at risk.

Description

Eating disorders are largely psychological disorders. They develop when a person has an unrealistic attitude toward or abnormal perception of his or her body. This causes behaviors that lead to destructive eating patterns that have negative physical and emotional consequences. Individuals with eating disorders often hide their symptoms and resist seeking treatment. Depression, **anxiety disorders**, and other mental illnesses often are present in people who have eating disorders, although it is not clear whether these cause the eating disorder or are a result of it.

The two best-known eating disorders, anorexia nervosa and bulimia nervosa, have formal diagnostic criteria and are recognized as psychiatric disorders in the *Diagnostic and Statistical Manual for Mental Disorders*, fifth edition (*DSM-5*) published by the American Psychiatric Association (APA). Other eating disorders have recognized sets of symptoms, but have not been researched thoroughly enough to be considered separate psychiatric disorders as defined by the APA.

WWW.BOOKBAZ.IR

Well-known eating disorders

In North America and Europe, anorexia nervosa is the most publicized of all eating disorders. It gained widespread public attention with the rise of the ultra-thin fashion model. People who have anorexia nervosa are obsessed with body weight. They constantly monitor their food intake and starve themselves to become thin. No matter how much weight they lose, they continue to restrict their calorie intake in an effort to become ever thinner. Some people with anorexia overexercise or abuse drugs or herbal remedies that they believe will help them burn calories faster. A few purge their bodies of the few calories they do eat by abusing **laxatives**, **enemas**, and **diuretics**. In time, they reach a point where their health is seriously, and potentially fatally, impaired.

People with anorexia nervosa have an abnormal perception of their body. They genuinely believe that they are larger than they are, even if they are life-threateningly thin. People with anorexia may deny that they are too thin, or, if they admit they are thin, deny that their behavior is affecting their health. People with anorexia will lie to family, friends, and health-care providers about how much they eat. Many vigorously resist treatment and accuse the people trying to cure them of wanting to make them fat. Anorexia nervosa is the most difficult eating disorder to recover from.

Bulimia nervosa is the only other eating disorder with specific diagnostic criteria defined by the *DSM-5*. People with bulimia often consume unreasonably large amounts of food in a short time. Afterwards, they purge their body of calories. This is done most often by self-induced **vomiting**, often accompanied by laxative abuse. A subset of people with bulimia does not vomit after eating, but fast and **exercise** obsessively to burn calories. Both behaviors result in impaired health.

People with bulimia feel out of control when they are binge eating. Unlike people with anorexia, they recognize that their behavior is abnormal. Often they are ashamed and feel guilty about their behavior and will go to great lengths to hide their binge/purge cycles from their family and friends. People with bulimia are often of normal weight. Although their behavior results in negative health consequences, because they are less likely to be ultrathin, these consequences are less likely to be life-threatening.

The APA does not formally recognize binge eating as an eating disorder. Binge eating is quite common, but it only rises to the level of a disorder when bingeing occurs at least twice a week for three months or more. People with binge eating disorder may eat thousands of calories in an hour or two. While they are eating, they feel out of control and may continue to eat long after they feel full. Unlike bulimia, people with binge eating disorder do not purge or exercise to get rid of the calories they have eaten. As a result, many people with binge eating disorder are obese, although not all obese people are binge eaters.

People with binge eating disorder may feel ashamed of their behavior and may try to hide it by eating in secret or hoarding food for future binges. After a binge, they usually feel guilty about their eating behavior. They might promise themselves that they will never binge again but are usually unable to keep this promise. Binge eating disorder often follows this seemingly endless cycle—rigorous dieting followed by an eating binge followed by guilt and rigorous dieting, followed by another eating binge. The main health consequences of binge eating are the development of obesity-related diseases such as type 2 diabetes, **sleep apnea**, **stroke**, and **heart attack**.

Lesser-known eating disorders

Quite a few eating problems are called disorders even though they do not have formal diagnostic criteria. They fall under the APA definition of eating disorders not otherwise specified. Many have only recently come to the attention of researchers and have been the subject of only a few small studies. Some have been known to the medical community for years but are rare.

Purge disorder is thought by some experts to be a separate disorder from bulimia. It is distinguished from bulimia by the fact that the individual maintains a normal or near normal weight despite purging by vomiting or laxative, enema, or diuretic abuse.

Anorexia athletica is a disorder of compulsive exercising. The individual places exercise above work, school, or relationships and defines his or her self-worth in terms of athletic performance. People with anorexia athletica also tend to be obsessed less with body weight than with maintaining an abnormally low percentage of body fat. This disorder is common among elite athletes.

Muscle dysmorphic disorder is the opposite of anorexia nervosa. Where people with anorexia believe that they are always overweight, people with muscle dysmorphic disorder believe that they are too small. This belief is maintained even when a person is clearly well-muscled. Abnormal eating patterns are less of a problem in people with muscle dysmorphic disorder than damage from compulsive exercising (even when

injured) and the abuse of muscle-building drugs such as anabolic **steroids**.

Orthorexia nervosa is a term coined by Steven Bratman, a Colorado physician, to describe "a pathological fixation on eating 'proper,' 'pure,' or 'superior' foods." People with orthorexia allow their fixation with eating the correct amount of properly prepared healthy foods at the correct time of day to take over their lives. This obsession interferes with relationships and daily activities. For example, they may be unwilling to eat at restaurants or friends' homes because the food is impure or improperly prepared. The limitations they put on what they will eat can cause serious vitamin and mineral imbalances. People with orthorexia may be judgmental about what other people eat to the point where it interferes with personal relationships. They justify their fixation by claiming that their way of eating is healthy. Some experts believe orthorexia may be a variation of **obsessive-compulsive disorder**.

Rumination syndrome occurs when an individual, either voluntarily or involuntarily, regurgitates food almost immediately after swallowing it, chews it, and then either swallows it or spits it out. Rumination syndrome is the human equivalent of a cow chewing its cud. The behavior often lasts up to two hours after eating. It must continue for at least one month to be considered a disorder. Occasionally the behavior simply stops on its own, but it can last for years.

Pica is the eating of non-food substances by people developmentally past the stage where this is normal (usually around age two). Earth and clay are the most common non-foods eaten, although people have been known to eat hair, feces, lead, laundry starch, chalk, burnt matches, cigarette butts, light bulbs, and other equally bizarre non-foods. This disorder has been known to the medical community for years, and in some cultures (mainly tribes living in equatorial Africa) is considered normal. Pica is most common among people with **intellectual disability** and developmental delays. It only rises to the level of a disorder when health complications require medical treatment.

Prader-Willi syndrome is a genetic defect that spontaneously arises in chromosome 15. It causes low muscle tone, short stature, incomplete sexual development, intellectual disability, and an uncontrollable urge to eat. People with Prader-Willi syndrome never feel full. The only way to stop them from eating themselves to death is to keep them in environments where food is locked up and not available. Prader-Willi syndrome is a rare disease, and although it is caused by a genetic defect, tends not to run in families, but rather is an accident of development. Fewer than 15,000 people in the United States have Prader-Willi syndrome.

"Drunkorexia," though not a medically recognized diagnosis, is the restriction of calories from food in order to consume greater amounts of alcohol without gaining weight. It is becoming increasingly common—a study conducted by professors at the University of Minnesota and published in the journal *Comprehensive Psychiatry* found that one in five students was substituting alcoholic beverages for meals. According to the U.S. Centers for Disease Control and Prevention, **binge drinking** is defined as having more than five drinks for men or four drinks for women in an short time frame. It is associated with a slew of adverse health effects, including higher risk of alcohol dependence, high blood pressure, stroke, **heart disease**, **liver disease**, neurological damage, sexual dysfunctions, injury (whether intentional or unintentional), and sexually transmitted diseases (due to lowered inhibitions while drunk). Replacing meals with alcohol can also place a person at risk of vitamin and nutrient deficiencies and **malnutrition**.

Causes and symptoms

Depression, low self-worth, and **anxiety** disorders are all common among people with eating disorders. Some disorders have obsessive-compulsive elements. The association between these psychiatric disorders and eating disorders is strong, but the cause and effect relationship is still unclear. Most specialists agree that eating disorders have multiple causes. There appears to be a genetic predisposition in some people toward developing an eating disorder. **Biochemistry** also seems to play a role. Neurotransmitters in the brain, such as serotonin, play a role in regulating appetite. Abnormalities in the amount of some neurotransmitters are thought to play a role in anorexia, bulimia, and binge eating disorder. Other disorders have not been studied enough to draw any conclusions.

Personality type can also put people at risk for developing an eating disorder. Low self-worth is common among people with eating disorders. Binge eaters and people with bulimia tend to have problems with impulse control and **anger management**. A tendency toward obsessive-compulsive behavior and black-or-white, all-or-nothing thinking also put people at higher risk.

Social and environmental factors also affect the development and maintenance of eating disorders and may trigger relapses during recovery. Relationship conflict, a disordered or unstructured home life, job

WWW.BOOKBAZ.IR

or school **stress**, and transitional events such as moving or starting a new job are all potential triggers for some people to begin disordered eating behaviors. Dieting (nutritional and social stress) is the most common trigger of all. The United States in the early twenty-first century is a culture obsessed with thinness. The media constantly send the message through words and images that being not just thin, but ultrathin, is fashionable and desirable. Magazines aimed mostly at women devote thousands of words every month to diet and exercise advice that creates a sense of dissatisfaction, unrealistic goals, and through airbrushing models to make them look thinner, many women develop a distorted **body image**.

Research has documented that comorbid illnesses and EDs tend to be diagnosed as a cluster of diagnoses; that is, patients with EDs often experience other psychiatric disorders. Axis I psychiatric disorders (including depression, anxiety, **body dysmorphic disorder**, or chemical dependency) and Axis II **personality disorders** (particularly **borderline personality disorder**) are frequently seen in the ED population. The breadth of these conditions increases the complexity of treatment and the skill required of the counselors and medical providers involved in the treatment.

Diagnosis

Diagnosis involves four components: a **health history**, a **physical examination** to rule out hormone abnormalities that may result in loss of weight, laboratory tests, and a mental status evaluation that also assesses suicidal risk. Health histories tend to be unreliable, because many people with eating disorders lie about their eating behavior, purging habits, and medication abuse. Based on the health history and a physical examination of the patient, the physician will order appropriate laboratory tests. Mental status can be evaluated using several different scales. The goal is to get an accurate assessment of the individual's physical condition and thinking in relationship to self-worth, body image, and food.

During the physical examination, other major medical complications may be diagnosed as well, such as cardiac arrhythmia, **dehydration** and electrolyte imbalances, delayed growth and development, endocrinological disturbances, gastrointestinal problems, oral health problems, osteopenia, **osteoporosis**, and protein/calorie malnutrition.

The mental health examination currently uses the *DSM-5*, which provides diagnostic criteria for psychiatric disorders, including certain eating disorders. Expanded diagnostic criteria is under consideration for the fifth edition (*DSM-5*), published in 2013. The *DSM* diagnostic criteria for anorexia nervosa includes an exaggerated drive for thinness, refusal to maintain a body weight above the standard minimum (e.g., 85% of expected weight), intense fear of becoming fat with self-worth based on weight or shape, and evidence of an endocrine disorder. The changes in *DSM-5* include restricted energy intake relative to requirements (leading to a markedly low body weight), intense fear of gaining weight or becoming fat or persistent behavior to avoid weight gain, and considerable distress regarding one's weight or body shape.

Criteria in the *DSM* for bulimia nervosa include overwhelming urges to overeat and inappropriate compensatory behaviors or purging that follow the binge episodes (e.g., vomiting, excessive exercise, alternating periods of **starvation**, and abuse of laxatives or drugs). Similar to anorexia nervosa, individuals with bulimia nervosa also display psychopathology, including a fear of being overweight. New criteria include recurrent episodes of binge eating with a sense of a lack of control with inappropriate compensatory behavior, self-evaluation that is unduly influenced by body shape and weight, and the specification that the behaviors do not occur exclusively during episodes of anorexia nervosa.

Treatment

Treatment depends on a collaborative approach by an interdisciplinary team of mental health, **nutrition**, and medical specialists. The degree to which the individual's health and mental status is impaired can direct what type of treatment plan is appropriate for the individual. People with EDs may need to be hospitalized or attend structured day programs for an extended period. Some people are also prescribed medication, but the mainstay of treatment is **psychotherapy**. An appropriate therapy is selected based on the type of eating disorder and the individual's psychological profile. Some of the common therapies used in treating eating disorders include:

- Cognitive behavior therapy (CBT) is designed to confront and then change the individual's thoughts and feelings about his or her body and behaviors toward food, but it does not address why those thoughts or feelings exist. Research has shown that CBT is effective for those with binge eating behaviors by decreasing the frequency of binges through helping the person learn to normalize their thought patterns and find compensatory responses to binging. However,

use of CBT with anorexia nervosa is compromised due to the addition of inborn disruptions in the person's neurotransmitter secretions, which places a limit on the extent to which CBT can assist in treatment.

- Psychodynamic therapy, also called psychoanalytic therapy, attempts to help the individual gain insight into the cause of the emotions that trigger their dysfunctional behavior. This therapy tends to be more long term than CBT.
- Interpersonal therapy is short-term therapy that helps the individual identify specific issues and problems in relationships. The individual may be asked to look back at his or her family history to try to recognize problem areas or stresses and work toward resolving them.
- Dialectical behavior therapy (DBT) consists of structured private and group sessions in which the therapist and patient(s) work at reducing behaviors that interfere with quality of life, finding alternate solutions to current problem situations, and learning to regulate emotions. In selected populations, some evidence suggests that DBT shows potential for decreasing binge eating and purging symptoms.
- Family and couples therapy can be helpful in dealing with conflict or disorders that may be a factor in perpetuating the eating disorder. Family therapy is especially useful in helping parents with anorexia to avoid passing on their attitudes and behaviors to their children. Self-esteem and assertiveness training may also be helpful in some patients with EDs.

Drugs

As of 2012, there were no medications approved by the U.S. Food and Drug Administration (FDA) for the specific treatment of anorexia nervosa. Medications prescribed for those with anorexia nervosa focus on either reducing anxiety or alleviating mood symptoms to assist the person in eating. For the treatment of bulimia nervosa, the FDA has approved fluoxetine after (or in conjunction with) behavior therapy.

Nutrition and dietary concerns

Eating disorders result in malnutrition that can have life-threatening consequences. Death may be due to cardiac arrhythmia, acute cardiovascular failure, gastric hemorrhaging, or **suicide**. Nutrition inadequacies commonly seen in the eating disorder group are low energy intake (which can be as severe as eating fewer than 500 calories per day), protein intake that results in clinical signs of protein deficiency, insufficient dietary **calcium** intake, fluid and electrolyte imbalances, and an array of vitamin and mineral insufficiencies.

KEY TERMS

Fast—A period of at least 24 hours in which a person eats nothing and drinks only water.

Type 2 diabetes—Sometimes called adult-onset diabetes, this disease prevents the body from properly using glucose (sugar).

Prognosis

Recovery from eating disorders can be a long, difficult process interrupted by relapses. About half of all people with anorexia relapse. Up to 20% die of complications of the disorder. The recovery rate for people with bulimia is slightly higher. Binge eaters experience many relapses and may have trouble controlling their weight even if they stop bingeing. Not enough is known about the other eating disorders to determine recovery rates. All eating disorders have serious social and emotional consequences. All except rumination disorder have serious health consequences. The sooner a person with an eating disorder gets professional help, the better the chance of recovery.

Prevention

Prevention involves both preventing and relieving stresses and enlisting professional help as soon as abnormal eating patterns develop. Some things that may help prevent an eating disorder from developing are listed below:

- Parents should not obsess about their weight, appearance, and diet in front of their children.
- Parents should not put their child on a diet unless instructed to by a pediatrician.
- Do not tease people about their body shapes or compare them to others.
- Make it clear that family members are loved and accepted as they are.
- Try to eat meals together as a family whenever possible; avoid eating alone.
- Avoid using food for comfort in times of stress.
- Monitor negative self-talk; practice positive self-talk.
- Spend time doing something enjoyable every day.
- Stay busy, but not overly busy; get enough sleep every night.

WWW.BOOKBAZ.IR

- Become aware of the situations that are personal triggers for abnormal eating behaviors and look for ways to avoid or defuse them.
- Do not go on extreme diets.
- Be alert to signs of low self-worth, anxiety, depression, and drug or alcohol abuse. Seek help as soon as these signs appear.

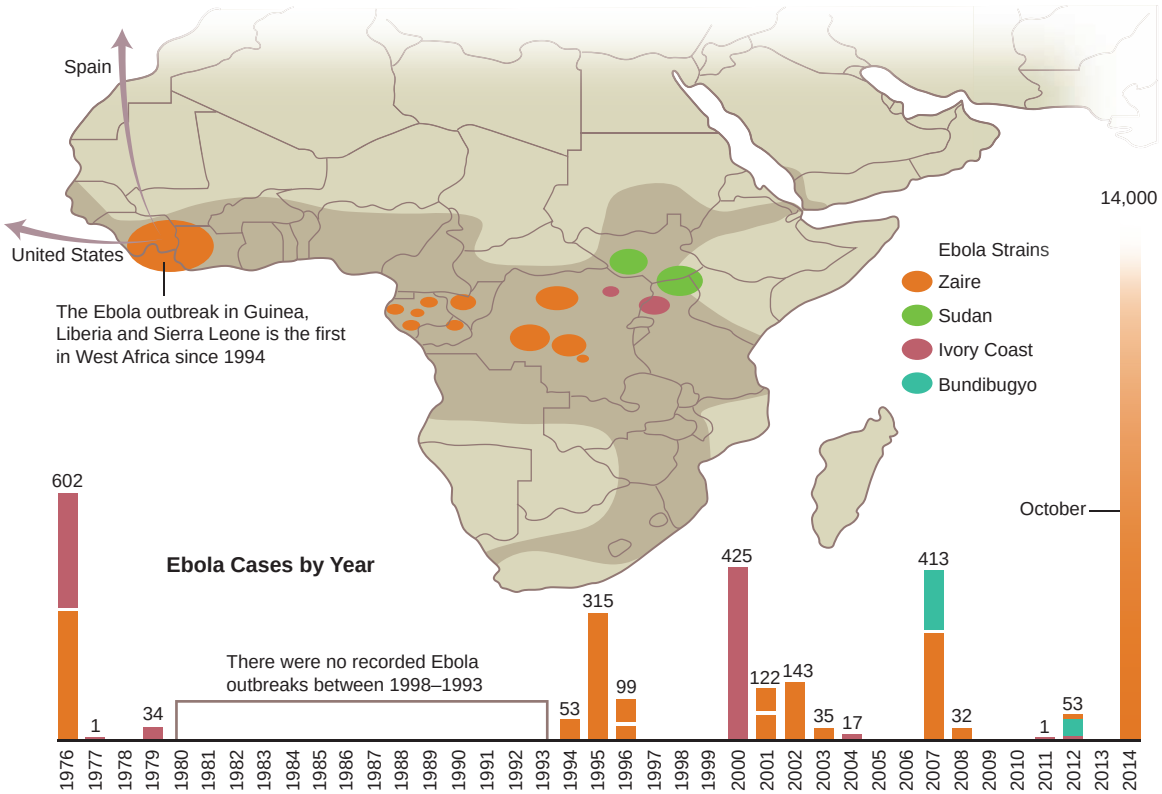
Ebola

Definition

Ebola is a severe—often fatal—viral disease that can be transmitted to humans from other mammals and spreads rapidly through communities. Previously confined to relatively small outbreaks in rural areas of Central Africa, in 2014, Ebola reached West Africa, spreading through crowded urban areas, sickening and killing thousands of people, and severely challenging global **public health** responses. The 2014 outbreak has spread to other parts of the world, including Europe and the United States. Public health



(Illustration by Electronic Illustrators Group. © Cengage Learning®.)

organizations and health care professionals continue to struggle to address and contain the outbreak.

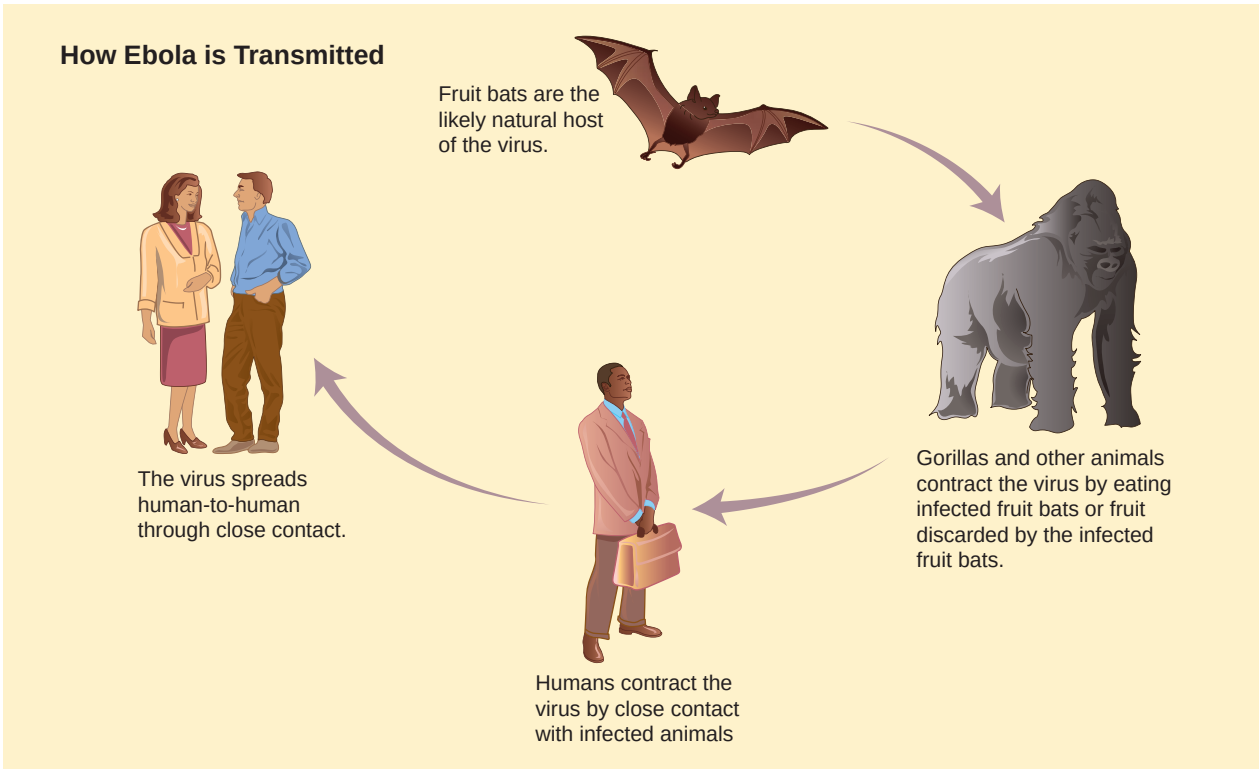
Demographics

Ebola was first identified in 1976 in Yambuku, a village near the Ebola River in what is now the Democratic Republic of Congo (DRC). The disease spread through close personal contact and contaminated needles and syringes, causing 318 cases with a fatality rate of 88%. A second outbreak caused by a different Ebola species occurred in the same year in Nzara, South Sudan. Over subsequent decades, small outbreaks occurred at intervals in rural areas of the DRC, Sudan, Gabon, Republic of Congo, and Uganda. Victims in these remote villages quickly died, and the outbreaks were limited by geographic **isolation**.

The self-limiting nature of Ebola outbreaks changed dramatically in 2014, when the virus reached West Africa. In December 2013 in a remote forest village in southeastern Guinea, a two-year-old boy sickened and died, but not before he had transmitted his disease to family members, a nurse, and friends and family attending the funerals. By the time the outbreak was identified as Ebola in March 2014, it had spread through other villages and towns to Conakry, Guinea's capital, and across borders to Sierra Leone and Liberia—borders that impoverished populations of the war-ravaged region crossed frequently to reach markets, visit relatives, and attend funerals. Having never seen Ebola, healthcare workers failed to recognize the disease and spread it themselves, with their deaths further depleting the meager supply of medical professionals. A 2014 Ebola outbreak in an isolated region of the DRC was unrelated to the West African outbreak.

By October 2014, there had been far more Ebola cases and deaths than in all other outbreaks combined—about 7,200 confirmed cases and more than 3,400 reported deaths. The actual numbers were two-to-three times higher, since the majority of cases went untreated and unreported. Although travelers carried Ebola from Liberia to Nigeria and from Guinea to Senegal, the rapid public-health response in those countries quickly contained the disease, and they were declared Ebola-free. But in Guinea, Sierra

WWW.BOOKBAZ.IR



(Illustration by Electronic Illustrators Group. © Cengage Learning®.)

Leone, and Liberia, lacking both trained personnel and public-health infrastructure, the disease—and panic—continued unabated. By September, Liberian cases were doubling every 15–20 days, and Sierra Leone and Guinea cases were doubling every 30–40 days. The U.S. Centers for Disease Control and Prevention (CDC) estimated that, without additional interventions and changes in community behavior, by January 2015, there would be a total of about 550,000 known cases in Liberia and Sierra Leone—about 1.4 million with corrections for underreporting. The fatality rate was projected at above 70%, although if aggressive treatment were available, it could be brought down to well below 50%. Estimates for Guinea were not possible, because there had been three separate waves of Ebola cases, each larger than the previous and probably reflecting importations of cases from Liberia and Sierra Leone. The World Health Organization (WHO) warned that Ebola could become endemic—continually present—in West Africa, a possibility that had never before been considered.

The West African Ebola crisis and its strain on already meager resources contributed to increases in illnesses and deaths from **childbirth** and **malaria** and other common diseases, as well as food shortages and the threat of complete societal breakdown. In September 2014, the United Nations Security Council unanimously declared Ebola a threat to international peace and security. That same month, a traveler from Liberia carried Ebola to Dallas, Texas, igniting a media-stoked frenzy. In early October, a Spanish nurse was infected by a patient returned from Sierra Leone, becoming the first person to contract Ebola outside of Africa. Subsequently, two health workers treating the Texas patient contracted the disease. One traveled via air to Ohio and back while experiencing symptoms of illness. Quarantine has been set up for those exposed in order to contain the number of cases transmitted in the United States.

Description

Ebola virus disease (EVD), formerly called Ebola hemorrhagic **fever**, affects humans and other primates, including monkeys, gorillas, and chimpanzees. Four of the five known Ebola species occur in animal hosts native to Africa. (The fifth species infects monkeys, pigs, and humans in the Philippines, but has not caused human illness.) The natural reservoir hosts of Ebola virus are probably fruit bats in the Pteropodidae family. Both primates and bats are hunted in West Africa. Some outbreaks have been traced to the hunting and

butchering of infected chimpanzees. The mining and timber industries, as well as deforestation resulting from civil wars in Liberia and Sierra Leone that sent refugees pouring into Guinea, have forced bats from their natural habitats into close proximity with humans. Once transmitted to humans, Ebola spreads through direct contact with infected blood or body secretions.

Scientists sequenced and analyzed 99 Ebola virus genomes from 78 patients in the 2014 outbreak. They concluded that the virus spread from Central Africa sometime in the past decade, followed by a single transmission event from an unknown animal to a human. Two viral lineages spread through human transmission from Guinea to Sierra Leone. Five of the scientists contributing to this work contracted EVD and died before the study was published.

Risk factors

Although some Ebola outbreaks have been traced to butchering and consuming bushmeat from infected animals, EVD spreads rapidly among family, friends, and healthcare workers, through contact with blood or body fluids. In contrast to earlier outbreaks, many healthcare workers died of Ebola in 2014, along with people caring for sick friends and family. African burial traditions that include bathing and touching the body further spread the disease.

Causes and symptoms

Causes

EVD in humans can be caused by four of the five known viruses in the genus *Ebolavirus* in the family Filoviridae:

- Ebola virus or Zaire ebolavirus, responsible for the 2014 West African outbreak
- Sudan virus
- Taï Forest virus, formerly *Côte d'Ivoire ebolavirus*
- Bundibugyo virus
- Reston virus, which first arrived into the United States in 1989 in monkeys imported from the Philippines

EVD progresses so rapidly that scientists have had difficulty determining the exact sequence of events, including the roles of some of the seven proteins that the viral RNA produces within host cells. The virus first interferes with the human immune response and then affects the vascular system. Upon entering the body, it infects dendritic cells—immune cells that would normally signal white blood cells called T cells to destroy infected cells and prevent the virus from spreading. The infected dendritic cells fail to signal T cells; T cells fail to respond or activate antibodies against the virus. This enables the virus to replicate (reproduce) very rapidly. An Ebola protein called VP24 also binds to and blocks a transport protein on the surfaces of immune cells, which inhibits interferon, an immune-system protein that stops viral replication. Immune-system cells called macrophages ingest the virus, but ingestion causes the macrophages to release proteins that trigger the formation of small clots throughout the blood vessels, which reduces blood supply to organs. The macrophages also produce inflammatory signaling proteins and nitric oxide, which damage blood vessels and cause them to leak—hence the name "hemorrhagic fever." Blood pressure drops.

In addition to triggering fever, body-wide inflammation, and sometimes hemorrhaging from the eyes, nose, and other body orifices, the virus targets other tissues, either by directly invading cells and destroying them from within or indirectly through the release of inflammatory molecules by macrophages and other immune cells. Ebola destroys liver cells that produce coagulation factors for halting bleeding and other important blood components. Damage to cells in the gastrointestinal tract causes **diarrhea** that leads to **dehydration**. Damage to cells in the adrenal gland prevents the production of **steroids** to control blood pressure, causing circulation failure that further starves organs for oxygen. Patients die from **shock** and multiple organ failure.

TRANSMISSION. Ebola is not spread through air, water, or food other than infected bushmeat. It can be transmitted to humans by infected mammals, such as primates, bats, forest antelope, and porcupines. It spreads among people through direct contact of infected blood or body fluids (urine, feces, vomit, semen, saliva, breast milk, or sweat) with broken skin or mucous membranes, including those of the eyes, nose, and mouth. It can also be spread through contaminated objects, such as needles, syringes, surfaces, or clothing and bedding contaminated with body fluids.

People are not infectious until they develop symptoms of Ebola, but they become more infectious as the disease progresses and remain infectious as long as their blood and body fluids retain the virus. The virus can be transmitted through semen for up to three months after recovery from the disease.

Symptoms

Symptoms appear two to 21 days after exposure to the virus, with an average of 8–10 days. First symptoms

WWW.BOOKBAZ.IR

are sudden onset of fever above 101.5°F (38.6°C), **fatigue**, joint and muscle **pain**, weakness, severe **headache**, and **sore throat**. These are followed by loss of appetite, **vomiting**, diarrhea, stomach pain, rash, red eyes, symptoms of kidney and liver dysfunction, and sometimes internal and external bleeding, such as bruising, bleeding from the gums, or blood in the stool.

Diagnosis

Examination

Early Ebola symptoms resemble those of other diseases more common in Africa, including malaria, **meningitis**, and **typhoid fever**. This can make diagnosis especially difficult when Ebola outbreaks coincide with malaria season. Sometimes Ebola is not suspected until malaria drugs fail to relieve symptoms.

Tests

Lab tests are required to confirm Ebola. Within a few days of symptom onset, diagnostic tests include:

- antigen-capture enzyme-linked immunosorbent assay (ELISA) or other tests to directly detect the virus
- IgM ELISA for detecting early antibodies against the virus
- serum-neutralization tests for anti-Ebola antibodies
- polymerase chain reaction (PCR) to detect viral genetic material
- virus isolation by cell culture
- electron microscopy to visualize the virus

Other laboratory diagnostic findings include low white blood cell and platelet counts and elevated liver enzymes in the blood. Later in the disease course or following recovery, IgM and IgG antibodies against Ebola can be detected. Immunohistochemistry, PCR, or virus isolation can be used for postmortem diagnosis.

Unfortunately, not only are these tests not widely available in African Ebola outbreaks, but samples for the tests are extreme biohazards that must be handled under maximum containment. As of 2014, several fast, easy, and inexpensive diagnostic tests were in development. They require only a few drops of blood from a finger prick and are easily carried to remote villages and for door-to-door screening. At least two such tests were scheduled to undergo field trials in Guinea and Sierra Leone in late 2014.

Treatment

Treatment is supportive care that provides the patient's immune system with the opportunity to launch a response, as well as treatment of complications. Survival is significantly improved by basic interventions early in the disease:

- oral and intravenous (IV) fluids and balancing of electrolytes (salts) to treat dehydration
- maintenance of blood oxygen and blood pressure
- treatment of other infections that may develop

Drugs

As of 2014, there were no approved drugs for treating Ebola, although several drugs and vaccines were under development. Some healthcare workers

KEY TERMS

Antibodies—Specific proteins produced by the immune system in response to specific foreign proteins or viruses.

Dendritic cells—Antigen-presenting cells that stimulate T cells and are infected by Ebola.

Endemic—Restricted or peculiar to a specific locale or region; especially a disease that is prevalent only in particular populations.

Enzyme-linked immunosorbent assay; ELISA—An immunological test for detecting specific substances, including viruses and antibodies.

Epidemic—Affecting many individuals in a community or population and spreading rapidly.

Filoviruses—The family of viruses that includes Ebola and hemorrhagic-fever viruses.

Immunoglobulin M; IgM—A type of antibody that is produced early in an infection.

Interferon—An immune-system anti-viral cytokine.

Macrophage—A large white blood cell, found primarily in the bloodstream and connective tissue, that ingests disease-causing organisms.

Outbreak—A sudden increase in the incidence of a disease.

Polymerase chain reaction; PCR—A method used to directly detect and quantify viral genetic material in the blood by amplifying (making numerous copies) of a portion of its RNA or DNA.

Reservoir—An animal species that harbors a virus, usually without symptoms of infection, and can transmit it to humans, either directly or via a vector.

T cells—T lymphocytes; immune-system white blood cells that help coordinate immune responses.

and others were treated in 2014 with experimental drugs such as ZMapp; however, supplies of such drugs were quickly exhausted. Furthermore, it was impossible to determine whether the drugs were responsible in patients who recovered. Rushing drugs and vaccines into the field before they were adequately tested for safety and effectiveness could potentially further stoke fears among many Africans that foreigners were infecting or otherwise harming them. As of October 2014, WHO was considering treating people with serum from recovered patients, which presumably contained potent anti-Ebola antibodies.

Prognosis

Fatality rates in previous Ebola outbreaks ranged from 25–90%, with an average rate of about 50%. Recovery is dependent on the patient's immune response and the availability of high-quality supportive care. Unfortunately, good clinical care was available to only a small minority of patients in the 2014 outbreak. Some people who recover have developed long-term complications, such as vision and joint problems.

Studies have found that recovered patients had higher levels of activated T cells, as well as specific variants of a gene that encodes white-blood-cell surface proteins that are involved in cellular communication. There also appears to be an association between survival and the levels of a platelet protein called sCD40L, which may be involved in repairing damaged blood vessels. Patients who recover from Ebola appear to have antibodies that protect them from re-infection for at least ten years. However, it is not clear whether they have immunity to other Ebola species or strains.

Global response

Containment of Ebola outbreaks is dependent on both an aggressive global public health response and the cooperation and involvement of the community. In the 2014 Ebola crisis, global response was both too little and too late. As early as March, Doctors Without Borders, the organization with the most experience in Ebola outbreaks, sounded the alarm that this new outbreak was fundamentally different. WHO warned against inciting panic. It was not until September that WHO, the United States, and other Western countries began to respond with desperately needed medical supplies and personnel. On September 16, U.S. President Barack Obama announced $750 million in aid and 3,000 military personnel for medical and logistic support. With far too few centers for handling Ebola patients—and bodies being left in the streets—most of the aid was directed at increasing patient beds and healthcare workers. However, with so many healthcare workers contracting Ebola, recruiting new workers locally and from overseas proved very difficult. Supplemental homecare kits were provided to help protect people caring from infected family members. The CDC predicted that if 70% of patients could be isolated in Ebola treatment units or other medical facilities—or when those were filled, cared for at home or in community settings that reduced the risk of disease transmission and provided safe burials—the epidemic would slow and eventually disappear. However, given that an estimated 60% of Ebola victims were not even being identified, the outlook appeared grim.

The initial response from some airlines and other transportation companies of suspending all service to affected countries made it that much more difficult to get supplies and workers to the most hard-hit regions. As of October, it was unclear whether travel restrictions and "no-touch" body-temperature screenings of passengers departing and arriving from affected countries would prevent the spread of Ebola to other parts of the world.

Community response

Community education and support is essential for ensuring that Ebola victims are taken to appropriate facilities, if possible, or isolated at home. Distrust of healthcare workers was a major impediment in the 2014 outbreak. Widely disseminated rumors claimed that Ebola did not exist or that the treatment centers were death traps for harvesting organs. Health workers were attacked and some killed, and there were clashes with security forces. Drastic Liberian measures, including quarantining a sprawling Monrovia slum for 11 days, increased distrust of the government and public health officials. Hope is also essential: affected communities must be made aware that by seeking treatment patients have a reasonable chance of surviving Ebola—and there must be enough beds for those seeking treatment. The public may also be required to defy tradition, not only avoiding physical contact with their friends and family, but also abandoning burial rituals that include washing and touching the body. As many as 365 Ebola infections were traced to a single funeral in Sierra Leone.

Containment of the 2014 Nigerian outbreak—in which an ill man flew into Lagos and transmitted Ebola to 19 or 20 others—was credited to rapid response by Nigerian officials collaborating with WHO, Doctors

WWW.BOOKBAZ.IR

Without Borders, UNICEF, and the CDC, as well as to the country's **polio** eradication campaign that included a state-of-the-art emergency command center built by the Bill & Melinda Gates Foundation and other medical facilities. The trained Nigerian rapid-response team set up safe wards with protective gear and trained health workers who made over 18,000 visits to 900 potential contacts. The response also included a massive public education campaign. The Ebola recovery rate in Nigeria was 60%, and most Ebola patients did not infect anyone else.

Prevention

Preventive measures include:

- avoiding travel to Ebola-affected areas
- frequent hand washing with soap and water or an alcohol-based sanitizer
- isolating people with early symptoms and notifying public-health authorities
- avoiding contact with blood and body fluids of anyone who is ill
- avoiding contact with contaminated surfaces, clothing, bedding, and medical equipment and supplies
- never touching the body of an Ebola victim
- never touching bats or primates, their blood or body fluids, or raw meat from such animals
- seeking immediate medical care and limiting contact with others if symptoms develop

Identified Ebola patients must be isolated and all of their contacts tracked down and monitored for symptoms for 21 days. People who recover from Ebola should abstain from sex or use **condoms** for three months. Healthcare workers exposed to Ebola patients must:

- isolate patients
- wear protective clothing—gowns, gloves, masks, and eye protection
- use dedicated medical equipment, preferably disposable
- practice proper sterilization and infection control
- follow proper procedures for cleaning, sterilizing, and disposing of all medical instruments, needles, and syringes
- avoid direct contact with bodies of Ebola victims
- notify health officials if they have direct contact with contaminated blood or body fluids

The U.S. National Institutes of Health began initial testing of a potential Ebola vaccine in September 2014. Human trials were to begin in early 2015.

Echinacea

Definition

Echinacea is the term given to several plants in the Asteraceae/Compositae family. It is known as the coneflower, narrow-leaf cone-flower, and black susan.

Description

Echinacea is native to, and abundant in, the North American prairie. The plants are indigenous, perennial herbs in North America and thrive when planted in temperate climates in Europe and Asia.

Echinacea propagates easily from seed or root cuttings.

Purpose

Native Americans chewed Echinacea roots to relieve toothaches and inflamed gums. They used teas of the roots and leaves to relieve stomach pains, treat colds and infections, and heal skin **wounds** and infections.

European herbalists and physicians have used Echinacea for over a hundred years to treat colds and respiratory and urinary infections, and to treat wounds.

Echinacea is second only to Ginko in herbal sales in the U.S.

Preparations

The quality and potency of herbal supplements depends on the soil and weather conditions where the herb is grown, the timing and care in harvesting it, and the manner in which it is prepared and stored.

Echinacea has been clinically tested for a number of conditions, including preventing and treating colds and respiratory infections, cancer, boosting immune systems, increasing white blood counts after **radiation therapy**, inflammation of the eye, vaginal yeast infections, and **genital herpes**.

In all of those conditions, clinical study results are, at best, inconclusive. It does not appear to prevent colds.

For treating colds, capsules containing from 300-1,200 mg can be taken per day for 7 days.

Precautions

Though used as medicines, herbal products like Echinacea are regulated like dietary supplements in the United States. Thus, manufacturers are responsible only for their production processes. Imported herbals may not meet U.S. manufacturing standards. Approval of herbals is based on traditional use, not demonstrated safety and effectiveness. Before an herbal can be forcefully withdrawn from the market, the FDA must prove that it is unsafe.

Many herbal products vary from stated label potency.

Side effects

People who are allergic to ragweed, mums, marigolds or daisies, or who have **asthma** may also react negatively to Echinaceae.

In therapeutic doses, Echinacea is generally safe. Approximately 1% of people taking the herb experience mild abdominal discomfort.

Interactions

Drug-herbal and herbal-herbal interactions are not well understood and have not been thoroughly tested. Patients must be careful observers of themselves for changes as they take new drugs or herbs, or as they take these products over many months.

James Waun, MD, RPh

Echinococcosis

Definition

Echinococcosis (Hydatid disease) refers to human infection by the immature (larval) form of tapeworm, *Echinococcus*. One of three forms of the *Echinococcus* spp., *E. granulosus*, lives on dogs and livestock, and infects humans through contact with these animals. Allergic reactions and damage to various organs from cyst formation are the most common forms of disease in humans.

Description

E. granulosus is found in many areas of Africa, China, South America, Australia, New Zealand, and Mediterranean and eastern Europe, as well as in parts of the western United States. The parasite lives in regions where dogs and livestock cohabitate. Direct exposure to infectious dogs, as well as parasitic eggs released into the environment during shedding, are both sources of human infection.

In humans, cysts containing the larvae develop after ingestion of eggs. Cysts form primarily in the lungs and liver. Cysts developing in the liver are responsible for about two-thirds of echinococcosis cases. Echinococcosis is a significant **public health** problem in many areas of the world, but control programs have decreased the rate of infection in some regions. In Kenya alone, the numbers of persons infected each year is as high as 220 per 100,000 population.

Causes and symptoms

After ingestion, the eggs develop into embryos within the intestines and then travel to the liver and lungs through major blood vessels. The embryos then begin to form cysts within the liver and lungs, causing damage as they enlarge over a period of five to 20 years. Cysts may become over 8 in (20.3 cm) or more in size and contain a huge amount of highly allergenic fluid. Studies show that while the liver is most often targeted, lungs, brain, heart, and bone can also be affected.

The major symptoms are due to compression damage, blockage of vessels and ducts (such as the bile ducts), and leakage of fluid from cysts. The following symptoms are frequent.

- Liver involvement causes pain and eventually jaundice or cholangitis due to blockage of bile ducts. Infection of cysts leads to abscesses in up to 20%.
- Lung cysts cause cough and chest pain.
- Bone cysts cause fractures and damage to bone tissue.
- Heart involvement leads to irregularities of heart beat and inflammation of the covering of the heart (pericardium).
- Allergic reactions occur from leakage of cyst fluid that contains antigens. Itching, fever, and rashes are frequent, and fatal allergic reactions (anaphylaxis) have been reported. Eosinophils, which are blood cells involved in allergic reactions, are increased in many patients.

KEY TERMS

Allergenic—A substance capable of causing an allergic reaction.

Cholangitis—Infection or inflammation of the bile ducts; often causes abdominal pain, fever, and jaundice.

Computed tomography (CT) scan—A specialized x-ray procedure in which cross-sections of the area in question can be examined in detail.

Cyst—A protective sac that includes either fluid or the cell of an organism. The cyst enables many organisms to survive in the environment for long periods of time without need for food or water.

Embryo—The very beginning stages of development of an organism.

Jaundice—The yellow-greenish coloring of the skin and eyes due to the presence of bile pigments. The presence of jaundice is usually, but not always, a sign of liver disease.

Tapeworm—An intestinal parasite that attaches to the intestine or travels to other organs such as the liver and lungs.

Ultrasound—A noninvasive procedure based on changes in sound waves of a frequency that cannot be heard, but respond to changes in tissue composition.

Diagnosis

X rays, **computed tomography scans** (CT scans), and **ultrasound** are very helpful in detecting cysts. Some cysts will develop characteristic hardening of organ tissues from **calcium** deposits (calcifications). Blood tests to detect antibodies are useful when positive, but up to 50% of patients have negative results. Examination of aspirated cyst fluid for parasites can be diagnostic, but carries the danger of a fatal allergic reaction. Treatment with anti-parasitic medications before aspiration is reported to decrease allergic complications and decrease the risk of spread during the procedure.

Treatment

Treatment depends on the size and location of cysts, as well as the symptoms they are producing. Surgical removal of cysts and/or surrounding tissue is the accepted method of treatment, but carries a risk of cyst rupture with spread or allergic reactions. Recent studies using medication alongside aspiration and drainage of cysts instead of surgery are very encouraging.

The medication albenzadole can be taken before or after surgery or alone without surgery. However, its effectiveness as a single treatment is still not known. Multiple courses of medication are often necessary, with cure rates of only about 30%. Response to treatment is best monitored by serial CT scans or similar x-ray studies.

Prevention

Good hand washing, treating infected dogs, and preventing dogs' access to slaughter houses discourage spread of the disease. Limiting the population of stray dogs has also been helpful.

Echocardiography

Definition

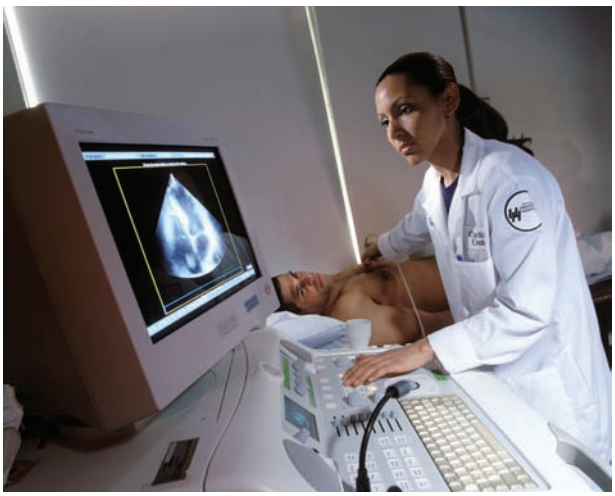
Echocardiography is a noninvasive diagnostic test that uses **ultrasound** waves to produce a moving image of the heart.

Purpose

Echocardiography is one of the most widely used diagnostic tests for **heart disease**. Ultrasound waves generated by a device placed on the skin rebound or echo off the heart and are processed by a computer. The resulting image can show the size, shape, and movement of the heart's valves and chambers, as well as the flow of blood through the heart.

Echocardiography may reveal abnormalities such as damage to the heart tissue from a **heart attack** or a poorly functioning heart valve. Echocardiography is especially useful for assessing disorders of the heart valves. It not only allows doctors to evaluate the condition of the heart valves, but can also show abnormalities in the pattern of blood flow. For example,

WWW.BOOKBAZ.IR



A patient during an echocardiography test. *(© Yoav Levy/ Phototake.—All rights reserved.)*

echocardiography can show the backward flow of blood through heart valves that remain partially open and should be fully closed.

By assessing the motion of the heart wall, echocardiography can help detect the presence and assess the severity of **coronary artery disease**, as well as help determine whether chest **pain** is related to heart disease. Additionally, echocardiography can help detect **hypertrophic cardiomyopathy**, a condition in which the walls of the heart thicken in an attempt to compensate for heart muscle weakness.

Echocardiography is also used to evaluate **heart murmurs** (abnormal heart sounds), determine the causes of **congestive heart failure**, assess enlarged hearts and hearts with septal defects (holes between pumping chambers), and monitor the heart in patients with diseases that may affect heart function (e.g., lupus erythematosus, lung diseases). The biggest advantage to echocardiography is that it is noninvasive (it does not involve breaking the skin or entering body cavities), and it has no known risks or side effects. It also gives a more detailed picture of the heart than other imaging techniques. Echocardiography is often used in conjunction with other diagnostic tests for the heart such as **electrocardiography**.

Echocardiography is usually performed in the cardiology department at a hospital, but may also be performed in a cardiologist's office or an outpatient imaging center. Because the ultrasound scanners used to perform echocardiography are portable (handheld) or mobile, echocardiography can be performed in a hospital emergency department or at the bedside of patients who cannot be moved.

Description

Echocardiography creates an image of the heart using ultra-high-frequency sound waves—sound waves that are too high in frequency to be heard by the human ear. The technique is very similar to ultrasound scanning commonly used to visualize the fetus during **pregnancy**.

An echocardiography examination generally lasts 15–30 minutes. The patient lies bare-chested on an examination table. A special gel is spread over the chest to help the transducer make good contact and slide smoothly over the skin. The transducer, also called a probe, is a small handheld device at the end of a flexible cable. The transducer is placed against the chest and directs ultrasound waves into the chest. Some of the waves get echoed (or reflected) back to the transducer. Since different tissues and blood reflect ultrasound waves differently, these returning sound waves can be translated into a meaningful image of the heart that is displayed on a monitor and recorded. The patient does not feel the sound waves, and the entire procedure is painless.

Occasionally, variations of the echocardiography test are used. For example, Doppler echocardiography employs a special transducer that allows technicians to measure and analyze the direction and speed of blood flow through blood vessels and heart valves. This makes it especially useful for detecting and evaluating backflow through the heart valves. By assessing the speed of blood flow at different locations around an obstruction, it can also help to precisely locate the obstruction.

An exercise echocardiogram, or stress echo, is an echocardiogram performed during exercise, when the heart muscle must work harder to supply blood to the body. This allows doctors to detect heart problems that might not be evident when the body is at rest and needs less blood. For patients who are unable to exercise, certain drugs can be used to mimic the effects of exercise by dilating the blood vessels and making the heart beat faster.

A transesophageal is done when it is difficult to get a clear picture of the heart using standard electrocardiogram techniques (e.g., interference from internal scar tissue, **obesity**). A transducer is attached to an endoscope, a thin tube that is threaded down the throat after it has been numbed. This position allows a clearer picture of the heart.

KEY TERMS

Lupus erythematosus—A chronic autoimmune disease that affects the skin, joints, and certain internal organs.

During the examination, a trained sonographer takes measurements and, using the ultrasound scanner's computer, makes calculations and measures blood flow speed. Most ultrasound scanners are equipped with videotape recorders or digital imaging/archiving devices to record the real-time examination and medical image printers to print out hard copies of still images. Information from the echocardiogram is then evaluated by a cardiologist.

Preparation

The patient removes any clothing and jewelry above the waist.

Aftercare

No special measures need to be taken following echocardiography. The procedure is painless.

Risks

There are no known complications associated with the use of echocardiography. There is a slight risk of heart attack during an exercise echocardiogram due to the stress put on the heart during the test, mostly for patients with a history of heart attack or other risk factors.

Results

A normal echocardiogram shows a normal heart structure and the normal flow of blood through the heart chambers and heart valves. However, a normal echocardiogram does not rule out the possibility of certain types of heart disease.

An echocardiogram may show a number of abnormalities in the structure and function of the heart, including:

- thickening of the wall of the heart muscle (especially the left ventricle)
- abnormal motion of the heart muscle
- blood leaking backward through the heart valves
- decreased blood flow through a heart valve due to narrowing of the valve (stenosis)

Ectopic pregnancy

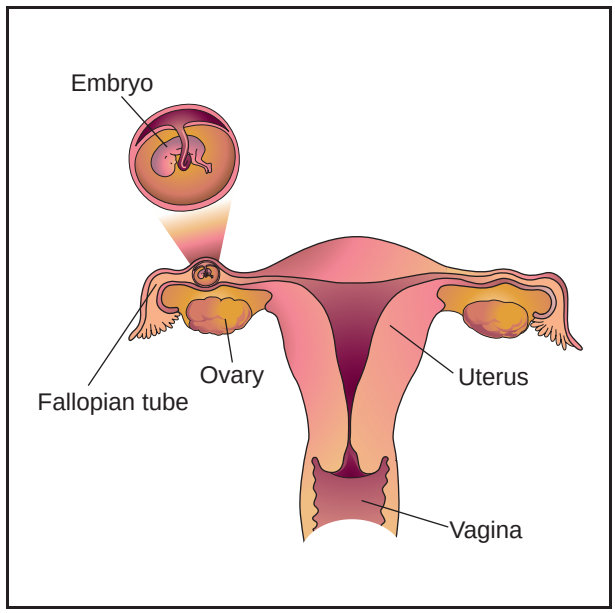
Definition

In an ectopic **pregnancy**, the fertilized egg implants in a location outside the uterus and tries to develop there. The word ectopic means "in an abnormal place or position." The most common site is the fallopian tube, the tube that normally carries eggs from the ovary to the uterus. However, ectopic pregnancy can also occur in the ovary, the abdomen, and the cervical canal (the opening from the uterus to the vaginal canal). The phrases tubal pregnancy, ovarian pregnancy, cervical pregnancy, and abdominal pregnancy refer to the specific area of an ectopic pregnancy.

Description

Once a month, an egg is produced in a woman's ovary and travels down the fallopian tube where it meets the male's sperm and is fertilized. In a normal pregnancy the fertilized egg, or zygote, continues on its passage down the fallopian tube and enters the uterus in three to five days. The zygote continues to grow, implanting itself securely in the wall of the uterus. The zygote's cells develop into the embryo (the organism in its first two months of development) and placenta (a spongy structure that lines the uterus and nourishes the developing organism).

In a tubal ectopic pregnancy, the fertilized egg cannot make it all the way down the tube because of scarring or obstruction. The fallopian tube is too narrow for the growing zygote. Eventually the thin walls of the tube stretch and may burst (rupture), resulting in severe bleeding and possibly the death of the mother. More than 95% percent of all ectopic pregnancies occur in the fallopian tube. Only 1.5% develop in the abdomen; less than 1% develop in the ovary or the cervix.



In an ectopic pregnancy, the fertilized egg implants in a location outside the uterus and attempts to develop at that site. The most common site of an ectopic pregnancy is the fallopian tube, but it can occur in the ovary, the abdomen, and the cervical wall. *(Illustration by Electronic Illustrators Group. © Cengage Learning®.)*

Causes and symptoms

As many as 50% of women with ectopic pregnancies have a history of **pelvic inflammatory disease** (PID). This is an infection of the fallopian tubes (salpingitis) that can spread to the uterus or ovaries. It is most commonly caused by the organisms *Gonorrhea* and *Chlamydia* and is usually transmitted by sexual intercourse.

Other conditions also increase the risk of ectopic pregnancy. They include:

- Endometriosis. A condition in which the tissue that normally lines the uterus is found outside the uterus, and can block a fallopian tube.
- Exposure to diethylsilbestrol (DES) as a fetus. If a woman's mother took DES (a synthetic version of the hormone estrogen) during pregnancy, the woman may have abnormalities in her fallopian tubes that can make ectopic pregnancy more likely.
- Taking hormones. Estrogen and progesterone are hormones that regulate the menstrual cycle and may be in medications prescribed by a doctor for birth control or other reasons. Taking these

hormones can affect the interior lining of the fallopian tubes and slow the movement of the fertilized egg down the tube. Women who become pregnant in spite of taking some progesterone-only contraceptives have a greater chance of an ectopic pregnancy. Ectopic pregnancy is also more likely when the ovaries are artificially stimulated with hormones to produce eggs for in vitro fertilization (a procedure in which eggs are taken from a woman's body, fertilized, and then placed in the uterus in an attempt to conceive a child).

- Use of an intrauterine device (IUD). These contraceptive devices are designed to prevent fertilized eggs from becoming implanted in the uterus, but they have only a minimal effect on preventing ectopic pregnancies. Therefore, if a woman becomes pregnant while using an IUD for contraception, the fertilized egg is more likely to be implanted someplace other than the uterus. For example, among women who become pregnant while using a progesterone-bearing IUD, about 15% have ectopic pregnancies.
- Surgery on a fallopian tube. The risk of ectopic pregnancy can be as high as 60% after undergoing elective tubal sterilization, a procedure in which the fallopian tubes are severed to prevent pregnancy. Women who have successful surgery to reverse the procedure are also more likely to have an ectopic pregnancy.

Early symptoms

In an ectopic pregnancy all the hormonal changes associated with a normal pregnancy may occur. The early symptoms include: **fatigue**; nausea; a missed period; breast tenderness; **low back pain**; mild cramping on one side of the pelvis; and abnormal vaginal bleeding, usually spotting.

Later symptoms

As the embryo grows too large for the confined space in the tube, the first sign that something is wrong may be a stabbing **pain** in the pelvis or abdomen. If the tube has ruptured, blood may irritate the diaphragm and cause shoulder pain. Other warning signs are lightheadedness and **fainting**.

Diagnosis

To confirm an early diagnosis of ectopic pregnancy, the doctor must determine first that the patient is pregnant and that the location of the embryo is outside the uterus. If an ectopic pregnancy is suspected, the doctor will perform a pelvic examination to locate the source of pain and to detect a mass in the abdomen.

Several laboratory tests of the patient's blood provide information for diagnosis. Measurement of the human chorionic gonadotropin (hCG) level in the patient's blood serum is the most useful laboratory test in the early stages. In a normal pregnancy, the level of this hormone doubles about every two days during the first 10 weeks. In an ectopic pregnancy, the rate of the increase is much slower and the low hCG for the stage of the pregnancy is a strong indication that the pregnancy is abnormal. (It could also represent a **miscarriage** in progress.) The level is usually tested several times over a period of days to determine whether or not it is increasing at a normal rate.

Progesterone levels in the blood are also measured. Lower than expected levels can indicate that the pregnancy is not normal.

An **ultrasound** examination may provide information about whether or not the pregnancy is ectopic. A device called a transducer, which emits high frequency sound waves, is moved over the surface of the patient's abdomen or inserted into the vagina. The sound waves bounce off of the internal organs and create an image on a screen. The doctor should be able to see whether or not there is a fetus developing in the uterus after at least five weeks of gestation. Before that point, a normal pregnancy is too small to see.

A culdocentesis may also help confirm a diagnosis. In this procedure a needle is inserted into the space at the top of the vagina, behind the uterus and in front of the rectum. Blood in this area may indicate bleeding from a ruptured fallopian tube.

A **laparoscopy** will enable the doctor to see the patient's reproductive organs and examine an ectopic pregnancy. In this technique, a hollow tube with a light on one end is inserted through a small incision in the abdomen. Through this instrument the internal organs can be observed.

Treatment

Ectopic pregnancy requires immediate treatment. The earlier the condition is treated, the better the chance to preserve the fallopian tube intact for future normal pregnancies.

Medical

If the ectopic pregnancy is discovered in a very early stage of development, the drug methotrexate may be given. The best results are obtained when the

WWW.BOOKBAZ.IR

pregnancy is less than six weeks old and the tubal mass is no more than 1.4 in (3.5 cm) in diameter. Methotrexate, which has been used successfully since 1987, works by inhibiting the growth of rapidly growing cells. (It is also used to treat some cancers.) Most side effects are mild and temporary, but the patient must be monitored after treatment. Usually the medication is injected into the muscle in a single dose, but may also be given intravenously or injected directly into the fallopian tube to dissolve the embryonic tissue. Methotrexate has also been used to treat ovarian, abdominal, and cervical pregnancies that are discovered in the early stages.

Surgical

When a laparoscopy is done to visualize the ectopic pregnancy, the scope can be fitted with surgical tools and used to remove the ectopic mass immediately after it is identified. The affected fallopian tube can be repaired or removed as necessary. This procedure can be done without requiring the patient to stay in the hospital overnight.

When the pregnancy has ruptured, a surgical incision into the abdomen, or laparotomy, is performed to stop the immediate loss of blood and to remove the embryo. This usually requires general **anesthesia** and a hospital stay. Every effort is made to preserve and repair the injured fallopian tube. However, if the fallopian tube has already ruptured, repair is extremely difficult and the tube is usually removed.

Alternatives

Ectopic pregnancy was first described in the eleventh century and was a potentially fatal condition until the advent of surgery and blood transfusions in the early twentieth century. The sophisticated diagnostic tools and surgical procedures developed since the 1970s have equipped modern medicine with the tools to not only save a woman's life, but also to preserve her future fertility.

Although there are herbal remedies for the temporary relief of the common symptoms of **anxiety** and abdominal discomfort, prompt medical treatment is the only sure remedy for ectopic pregnancy.

Prognosis

Ectopic pregnancies are the leading cause of pregnancy-related deaths in the first trimester and account for 9% of all pregnancy-related deaths in the United States. More than 1% of pregnancies are ectopic, and they are becoming more common. The reason for this increase is not clearly understood, though it is thought that the dramatic increase in sexually transmitted diseases (STD) is at least partly responsible.

The earlier an ectopic pregnancy is diagnosed and treated, the better the outcome. The chances of having a successful pregnancy are lower after an ectopic pregnancy, but depend on the extent of permanent fallopian tube damage. If the tube has been spared, chances are as high as 60%. The chances of a successful pregnancy after the removal of one tube are 40%.

Prevention

Many forms of ectopic pregnancy cannot be prevented. However, tubal pregnancies, which make up the majority of ectopic pregnancies, may be prevented by avoiding conditions that cause damage to the fallopian tubes. Since half of all women who experience ectopic pregnancy have a history of PID, avoiding this infection or getting early diagnosis and treatment for sexually transmitted diseases will decrease the risk of a future problem.

KEY TERMS

Embryo—In humans, the developing organism from conception until approximately the end of the second month.

Fallopian tube—The tube that carries the egg from the ovary to the uterus.

Human chorionic gonadotropin (hCG)—A hormone excreted during the development of an embryo or fetus.

Laparoscopy—Examination of the contents of the abdominal cavity with a fiberoptic tube inserted through a small incision.

Laparotomy—Surgical incision into the abdomen to locate, repair, and/or remove injured or diseased tissues.

Pelvic inflammatory disease (PID)—Acute or chronic inflammation in the pelvic cavity, particularly inflammation of the fallopian tubes (salpingitis) and its complications.

Rupture—A breaking apart of an organ or tissue.

Salpingitis—Inflammation of the fallopian tube.

Tubal pregnancy—Pregnancy in one of the fallopian tubes.

Zygote—The fertilized egg.

Karen Ericson, RN

Eczema

Definition

Eczema, also called **atopic dermatitis** (AD), is a non-contagious inflammation of the skin characterized by dry, red, itchy, and oozing lesions that become scaly, crusty, or hardened. Various other types of **dermatitis** are sometimes referred to as eczema or eczematous, although AD is the most common type.

Demographics

Worldwide 10–20% of people develop atopic dermatitis at some point in their lives. Although eczema can affect anyone at any age, it is most common in children under age five. An estimated 65% of eczema cases begin during the first year of life and 90% develop before the age of five. The incidence of eczema and other allergic diseases appears to have increased in recent decades. It is estimated that almost one in ten American babies develop eczema.

Description

Eczema is sometimes described as "the itch that rashes," because scratching irritated areas sometimes initiates a rash. Eczema can be mild and intermittent or severe and chronic, disappearing as children grow up or lasting a lifetime. Eczema is frequently related to some form of allergy, including **allergies** to foods or inhalants.

The areas of the body affected by eczema tend to vary with age. Infants frequently have eczema on the face and other areas of the head. The stomach and limbs also may be affected. Older children commonly have more severe eczema on flexor surfaces—the inner wrists and elbows, backs of the knees, and tops of the ankles, as well as the hands and feet. The knees, elbows, hands, and feet may continue to be a problem into adulthood. Occasionally eczema becomes widespread throughout the body.

Other types of dermatitis that may be described as eczematous, but which usually affect older children and adults, include:

- contact dermatitis, which results from skin contact with an irritant or allergen
- nummular dermatitis, which usually affects people over the age of 55
- stasis dermatitis, which results from poor circulation in the legs

Risk factors

The major risk factor for eczema appears to be a family history of eczema and/or allergies.

Causes and symptoms

In many cases the exact cause of eczema is unknown, although it often appears to result from an interaction between an inherited genetic predisposition towards allergies and exposure to specific environmental allergens, especially those that are inhaled or ingested.

The hallmark sign of eczema is a red, itchy rash and skin that is abnormally dry. Chronic or severe cases of eczema can result in thick plaques (patches of slightly raised skin), serous (watery) exudates, or infection.

Diagnosis

Examination

Eczema is diagnosed by the appearance and location of the rash. An individual or family history of allergies, including **food allergies**, hay **fever**, or **asthma**, supports the diagnosis of eczema.

Tests

There are no laboratory tests for diagnosing eczema. Sometimes dermatologists conduct skin tests—scratch or patch tests or intradermal injections—to attempt to identify suspected allergens. A small amount of the suspected allergen is dabbed, scratched, or pricked into the skin, usually on the back. If no irritation develops within a few days, patch tests for other suspected allergens may be performed sequentially. Blood tests can measure the levels of immunoglobulin E (IgE)—the antibodies involved in allergic reactions—and, in some cases, the levels of IgE that are specific for a given antigen.

WWW.BOOKBAZ.IR

KEY TERMS

Allergic reaction—An immune system reaction to a substance in the environment; symptoms include rash, inflammation, sneezing, itchy watery eyes, runny nose, or skin irritations.

Antigen—A foreign protein or particle that causes the body to produce specific antibodies that bind to the antigen.

Atopy—Allergies, such as eczema, that are probably hereditary, with symptoms that develop upon exposure to specific environmental allergens.

Corticosteroids—A group of hormones produced by the adrenal glands or manufactured synthetically. They are often used to treat inflammation. Examples include cortisone and prednisone.

Dermatitis—Inflammation of the skin.

Patch test—Scratch test; a test to identify allergens, in which the suspected substance is pricked or scratched into the skin and observed for the development of redness and swelling that are indicative of an allergic reaction.

Rash—Spotted, pink or red skin eruptions that may be accompanied by itching.

Procedures

In rare cases a **skin biopsy** may be required to rule out certain diseases.

Treatment

Traditional

The best treatment for eczema is to identify the cause and eliminate it. Since this is often not possible, medications and home treatments for hydrating the skin are the best options. Since **itching** or scratching eczema can irritate and damage the skin and cause **rashes**, any treatment that reduces the itching is helpful.

Drugs

Drug treatments for eczema include:

- oral antihistamines to decrease itching
- calamine lotion
- mild topical corticosteroids containing at least 1% hydrocortisone
- rarely, oral corticosteroids for severe itching and inflammation
- topical antibiotics to prevent or treat infection
- oral antibiotics for widespread infection
- topical pimecrolimus (Elidel) and tacrolimus (Protopic)—immunomodulators that may be used in adults and children over age two when other treatments have failed

Alternatives

Light therapy or **phototherapy** can effectively treat eczema, either by controlled exposure to natural sunlight or artificial ultraviolet A (UVA) and/or ultraviolet B (UVB) light. However a dermatologist should be consulted about the benefits and risks of phototherapy.

There are a number of alternative therapies that may prove helpful for treating eczema:

- acupuncture
- autogenic training, meditation, and self-hypnosis
- hypnotherapy—using the power of suggestion to relieve itching
- massage to reduce stress
- reflexology focusing on areas of the body corresponding to the eczema-affected patches, as well the solar plexus, adrenal glands, pituitary gland, liver, kidneys, gastrointestinal tract, and reproductive glands
- aromatherapy with small amounts of essential oils of lavender, bergamot, and geranium to decrease itching and inflammation; however improper dilutions of essential oils can worsen eczema
- evening primrose (*Oenothera biennis*) oil (EPO) diluted in a carrier oil and massaged into the skin

Herbal therapies that are often recommended for skin conditions such as eczema include:

- calendula (*Calendula officinalis*) ointment, for its anti-inflammatory and antiseptic properties
- chickweed (*Stellaria media*) ointment, to soothe itching
- evening primrose oil—topically to relieve itching and internally as a fatty acid supplement
- German chamomile (*Chamomilla recutita*) ointment, for its anti-inflammatory properties
- nettle (*Urtica dioica*) ointment, to relieve itching
- peppermint (*Menta piperita*) lotion, for its antibacterial and antiseptic properties
- traditional Chinese herbal formulas, both applied topically and taken internally, to moisten the skin, prevent itching, nourish the blood, and encourage healing.

Individuals vary in their responses to herbal treatments. Chronic, severe, or infected eczema requires the attention of a healthcare professional.

Various **nutritional supplements** may aid in treating eczema:

- Oral EPO, which contains gamma-linolenic acid, has been shown to significantly reduce itching from eczema at doses of approximately 6 grams (g) daily.
- Fish oil at a dose of about 1.8 g per day has been shown to improve AD.
- Vitamin C can promote both skin healing and the immune system. Doses of 50–75 milligrams per kilogram (mg/kg) of body weight have been shown to relieve symptoms of AD.
- Supplemental copper may be required with high doses of vitamin C.
- Vitamin E may be of use in treating eczema.

Home remedies

Home care for eczema focuses on keeping the skin clean and moist and avoiding irritants and known allergens as much as possible. Frequent long, tepid soaks help hydrate very dry skin; however soaking in plain water can be painful during severe episodes of eczema:

- Adding one-half cup of table salt to one-half tub of water creates a normal saline solution, similar to that present in the body tissues, and may relieve burning.
- Adding baking soda, a muslin bag filled with milled oats, or the commercial preparation Aveeno to the water can be soothing.
- Research has shown that dilute bleach baths—one-half cup (118 mL) of bleach in 40 gal (151 L) of warm water—can treat eczema by killing bacteria growing on the skin. The affected areas should be soaked for 5–10 minutes once or twice per week.
- Commercial Domeboro powder may be helpful.
- Bath water should cover as much of the skin as possible. Wet towels may be draped around the shoulders, upper trunk, and arms if they are above the water level.
- The face should be dabbed frequently during bathing to keep it moist.
- The use of soap should be minimized and limited to very mild agents such as Cetaphil.

Drying off should involve two–three minutes of gentle patting, followed by the thick application of a water-barrier ointment, such as Aquaphor, Unibase, or Vaseline. Oil or creams applied to damp skin can seal in moisture. However moisturizing lotions containing alcohol dry the skin and may burn when applied to eczema. Babies' skin should be kept lubricated with appropriate bath oils, lotions, creams, or ointments.

Soaking wraps are an alternative to bathing. Cotton towels or other cloths are soaked in tepid water, possibly containing table salt or Domeboro powder, and used to cover the bare skin as thoroughly as possible. The patient lies on a bed with a waterproof sheet and is covered by a second waterproof covering, such as vinyl sheeting or plastic wrap, to slow evaporation. The wraps are left in place for as long as possible, but for at least 30 minutes, followed by the application of a water barrier and any topical medications.

Environmental changes can provide relief for many eczema sufferers:

- Pet dander and cigarette smoke should be kept out of the home, or at least out of the room.
- Clothing should be loose fitting to prevent irritation from rubbing.
- Clothing and bedding should be 100% soft cotton.
- Clothing and bedding should be washed before initial use to rid them of potentially irritating residues.
- Laundry soap should by dye- and perfume-free.
- Laundry should be run through a double-rinse cycle to remove any vestiges of detergent.
- Bedding should be washed in hot water to kill dust mites, which can be major irritants to people with eczema.
- Fabric softener or dryer sheets are frequently scented and may be irritating.
- Clothes and bedding should not be dried outdoors where pollen and other potential allergens can cling to them.
- Mattresses and pillowcases can be covered by special casings that are impervious to microscopic dust mites.
- Dust-collecting items, such as curtains, carpeting, and stuffed animals, should be kept to a minimum.
- Vacuuming and dusting should be performed regularly when the patient is out of the room.

Temperature extremes can aggravate eczema, so heating and cooling should be employed appropriately, along with the use of a home humidifier. Eczema can interfere with normal body temperature regulation and can be aggravated by sweating. Central air-conditioning is preferable to evaporative cooling or open windows that can bring allergens into the house. Car air-conditioning is preferable to open windows. Electrostatic filters and vent covers can remove irritants from household air. These should be changed

WWW.BOOKBAZ.IR

or cleaned frequently. A HEPA filter unit and a vacuum with a built-in HEPA filter can remove a high percentage of the dust and pollen.

It is difficult to keep children from scratching and damaging irritated and itchy skin:

- Fingernails should be kept short, using a nail file for a smoother edge.
- Pajamas and clothing with maximum coverage help to protect the bare skin from fingernails.
- Mittens or socks can be used to prevent scratching at night.
- Infant gowns with hand coverings are useful for very young children.

Prognosis

Although there is no cure for eczema, most children improve with age, often by age five. For others however, eczema is a lifelong problem. Diligent daily skin care and avoidance of known triggers can largely control most cases. As many as 75% of children with eczema will develop other allergies, including hay fever, food allergies, or asthma.

Prevention

Breastfeeding an infant may help prevent eczema, particularly if there is a family history of eczema or allergies. It also may help for the breastfeeding mother to avoid foods that are common allergens. These include wheat, eggs, milk products, peanuts, and fish. If breastfeeding is not possible, a hypoallergenic formula should be used if there is family history of allergies.

Avoidance of known triggers and diligent skin care can minimize eczema flare-ups. A twice-daily emollient (moisturizing) routine should be followed even when the eczema appears to be under control. Eczematous skin is more susceptible to infection and patients should try to avoid contact with people infected with **chickenpox**, **cold sores**, and other contagious skin infections.

ED *see* **Erectile dysfunction**

Edema

Definition

Edema is a condition of abnormally large fluid volume in the circulatory system or in tissues between the body's cells (interstitial spaces).

Description

Normally the body maintains a balance of fluid in tissues by ensuring that the same of amount of water entering the body also leaves it. The circulatory system transports fluid within the body via its network of blood vessels. The fluid, which contains oxygen and nutrients needed by the cells, moves from the walls of the blood vessels into the body's tissues. After its nutrients are used up, fluid moves back into the blood vessels and returns to the heart. The lymphatic system (a network of channels in the body that carry lymph, a colorless fluid containing white blood cells to fight infection) also absorbs and transports this fluid. In edema, either too much fluid moves from the blood vessels into the tissues, or not enough fluid moves from the tissues back into the blood vessels. This fluid imbalance can cause mild to severe swelling in one or more parts of the body.

Causes and symptoms

Many ordinary factors can upset the balance of fluid in the body to cause edema, including:

- Immobility. The leg muscles normally contract and compress blood vessels to promote blood flow with walking or running. When these muscles are not used, blood can collect in the veins, making it difficult for fluid to move from tissues back into the vessels.
- Heat. Warm temperatures cause the blood vessels to expand, making it easier for fluid to cross into surrounding tissues. High humidity also aggravates this situation.
- Medications. Certain drugs, such as steroids, hormone replacements, nonsteroidal anti-inflammatory drugs (NSAIDs), and some blood pressure medications may affect how fast fluid leaves blood vessels.
- Intake of salty foods. The body needs a constant concentration of salt in its tissues. When excess salt is taken in, the body dilutes it by retaining fluid.
- Menstruation and pregnancy. The changing levels of hormones affect the rate at which fluid enters and leaves the tissues.

Some medical conditions may also cause edema, including:

- Heart failure. When the heart is unable to maintain adequate blood flow throughout the circulatory system, the excess fluid pressure within the blood vessels can cause shifts into the interstitial spaces. Left-sided heart failure can cause pulmonary edema, as fluid shifts into the lungs. The patient may develop rapid, shallow respirations, shortness of breath, and a cough. Right-sided heart failure can cause pitting edema, a swelling in the tissue under the skin of the lower legs and feet. Pressing this tissue with a finger tip leads to a noticeable momentary indentation.
- Kidney disease. The decrease in sodium and water excretion can result in fluid retention and overload.
- Thyroid or liver disease. These conditions can change the concentration of protein in the blood, affecting fluid movement in and out of the tissues. In advanced liver disease, the liver is enlarged and fluid may build-up in the abdomen.
- Malnutrition. Protein levels are decreased in the blood, and in an effort to maintain a balance of concentrations, fluid shifts out of the vessels and causes edema in tissue spaces.

Some conditions that may cause swelling in just one leg include:

- Blood clots. Clots can cause pooling of fluid and may be accompanied by discoloration and pain. In some instances, clots may cause no pain.
- Weakened veins. Varicose veins, or veins whose walls or valves are weak, can allow blood to pool in the legs. This is a common condition.

WWW.BOOKBAZ.IR

Gross lymphedema in the arm of an elderly woman following radiotherapy treatment for breast cancer. *(Dr. P. Marazzi/Photo Researchers, Inc.)*

- Infection and inflammation. Infection in leg tissues can cause inflammation and increasing blood flow to the area. Inflammatory diseases, such as gout or arthritis, can also result in swelling.
- Lymphedema. Blocked lymph channels may be caused by infection, scar tissue, or hereditary conditions. Lymph that can not drain properly results in edema. Lymphedema may also occur after cancer treatments, when the lymph system is impaired by surgery, radiation, or chemotherapy.
- Tumor. Abnormal masses can compress leg vessels and lymph channels, affecting the rate of fluid movement.

Symptoms vary depending on the cause of edema. In general, weight gain, puffy eyelids, and swelling of the legs may occur as a result of excess fluid volume. Pulse rate and blood pressure may be elevated. Hand and neck veins may be observed as fuller.

Diagnosis

Edema is a sign of an underlying problem, rather than a disease unto itself. A diagnostic explanation should be sought. Patient history and presenting symptoms, along with laboratory blood studies, if indicated, assist the health professional in determining the cause of the edema.

Treatment

Treatment of edema is based on the cause. Simple steps to lessen fluid build-up may include:

- Reducing sodium intake. A high sodium level causes or aggravates fluid retention.
- Maintaining proper weight. Being overweight slows body fluid circulation and puts extra pressure on the veins.
- Exercise. Regular exercise stimulates circulation.
- Elevation of the legs. Placing the legs at least 12 in (30.5 cm) above the level of the heart for 10–15 minutes, three to four times a day, stimulates excess fluid re-entry into the circulatory system.
- Use of support stocking. Elastic stockings, available at most medical supply or drug stores, will compress the leg vessels, promoting circulation and decreasing pooling of fluid due to gravity.

KEY TERMS

Digitalis—A naturally occuring compound used in the preparation of the medication, digoxin, prescribed to increase the heart rate and strengthen the force of the heart's contractions.

Diuretics—Medications used in the treatment of fluid overload, to promote excretion of sodium and water.

Interstitial spaces—Areas of the body occuring outside the vessels or organs, between the cells.

Pitting edema—A swelling in the tissue under the skin, resulting from fluid accumulation, that is measured by the depth of indentation made by finger pressure over a boney prominence.

- Massage. Massaging the body part can help to stimulate the release of excess fluids, but should be avoided if the patient has blood clots in the veins.
- Travel breaks. Sitting for long periods will increase swelling in the feet and ankles. Standing and/or walking at least every hour or two will help stimulate blood flow.

The three "Ds"–diuretics, digitalis, and diet—are frequently prescribed for medical conditions that result in excess fluid volume. **Diuretics** are medications that promote urination of **sodium** and water. **Digoxin** is a digitalis preparation that is sometimes needed to decrease heart rate and increase the strength of the heart's contractions. Dietary recommendations include less sodium in order to decrease fluid retention. Consideration of adequate protein intake is also made.

For patients with **lymphedema**, a combination of therapies may prove effective. Combined decongestive therapy includes the use of manual lymph drainage (MLD), compression bandaging, garments and pumps, and **physical therapy**. MLD involves the use of light massage of the subcutaneous tissue where the lymph vessels predominate. Massage begins in an area of the body trunk where there is normal lymph function and proceeds to areas of lymphatic insufficiency, in an effort to stimulate new drainage tract development. (MLD should not be used for patients with active cancer, deep vein clots, **congestive heart failure**, or cellulitis.) MLD sessions are followed by application of compression garments or pumps. Physical therapy is aimed at strengthening the affected limb and increasing joint mobility.

Alternatives

Dietary changes, in addition to cutting back the amount of sodium eaten, may also help reduce edema. Foods that worsen edema, such as alcohol, **caffeine**, sugar, dairy products, soy sauce, animal protein, chocolate, olives, and pickles, should be avoided. Diuretic herbs can also help relieve edema. One of the best herbs for this purpose is dandelion (*Taraxacum mongolicum*), since, in addition to its diuretic action, it is a rich source of potassium. (Diuretics flush potassium from the body and it must be replaced to avoid potassium deficiency.) **Hydrotherapy** using daily contrast applications of hot and cold (either compresses or immersion) may also be helpful.

Edrophonium test *see* **Tensilon test**

Edwards' syndrome

Definition

Edwards' syndrome is caused by an extra copy of chromosome 18. For this reason, it is also called trisomy 18 syndrome. The extra chromosome is lethal for most babies born with this condition. It causes major physical abnormalities and severe intellectual disabilities (ID), and very few children afflicted with this disease survive beyond a year.

Description

Humans normally have 23 pairs of chromosomes. Chromosomes are numbered 1–22, and the 23rd pair is composed of the sex chromosomes, X and Y. A person inherits one set of 23 chromosomes from each parent. Occasionally, a genetic error occurs during egg or sperm cell formation. A child conceived with such an egg or sperm cell may inherit an incorrect number of chromosomes.

In the case of Edwards' syndrome, the child inherits three, rather than two, copies of chromosome 18. Trisomy 18 occurs in approximately one in every 3,000 newborns and affects girls more often than

WWW.BOOKBAZ.IR

KEY TERMS

Aminocentesis—A procedure in which a needle is inserted through a pregnant woman's abdomen and into her uterus to withdraw a small sample of amniotic fluid. The amniotic fluid can be examined for signs of disease or other problems afflicting the fetus.

Chorionic villus sampling—A medical test that is best done during weeks 10–12 of a pregnancy. The procedure involves inserting a needle into the placenta and withdrawing a small amount of the chorionic membrane for analysis.

Chromosome—A structure composed of deoxyribonucleic acid (DNA) contained within a cell's nucleus (center) where genetic information is stored. Human have 23 pairs of chromosomes, each of which has recognizable characteristics (such as length and staining patterns) that allow individual chromosomes to be identified. Identification is assigned by number (1–22) or letter (X or Y).

Karyotyping—A laboratory test used to study an individual's chromosome make-up. Chromosomes are separated from cells, stained, and arranged in order from largest to smallest so that their number and structure can be studied under a microscope.

Maternal serum analyte screening—A medical procedure in which a pregnant woman's blood is drawn and analyzed for the levels of certain hormones and proteins. These levels can indicate whether there may be an abnormality in the unborn child. This test is not a definitive indicator of a problem and is followed by more specific testing such as amniocentesis or chorionic villus sampling.

Trisomy—A condition in which a third copy of a chromosome is inherited. Normally only two copies should be inherited.

Ultrasound—A medical test that is also called ultrasonography. Sound waves are directed against internal structures in the body. As sound waves bounce off the internal structure, they create an image on a video screen. An ultrasound of a fetus at weeks 16–20 of a pregnancy can be used to determine structural abnormalities.

boys. Women older than their early thirties have a greater risk of conceiving a child with trisomy 18, but it can occur in younger women.

Causes and symptoms

A third copy of chromosome 18 causes numerous abnormalities. Most children born with Edwards' syndrome appear weak and fragile, and they are often underweight. The head is unusually small and the back of the head is prominent. The ears are malformed and low-set, and the mouth and jaw are small. The baby may also have a **cleft lip** or **cleft palate**. Frequently, the hands are clenched into fists, and the index finger overlaps the other fingers. The child may have clubfeet and toes may be webbed or fused.

Numerous problems involving the internal organs may be present. Abnormalities often occur in the lungs and diaphragm (the muscle that controls breathing), and heart defects and blood vessel malformations are common. The child may also have malformed kidneys and abnormalities of the urogenital system.

Diagnosis

Physical abnormalities point to Edwards' syndrome, but definitive diagnosis relies on karyotyping. Karyotyping involves drawing the baby's blood or bone marrow for a microscopic examination of the chromosomes. Using special stains and microscopy, individual chromosomes are identified, and the presence of an extra chromosome 18 is revealed.

Trisomy 18 can be detected before birth. If a pregnant woman is older than 35, has a family history of genetic abnormalities, has previously conceived a child with a genetic abnormality, or has suffered earlier miscarriages, she may undergo tests to determine whether her child carries genetic abnormalities. Potential tests include maternal serum analysis or screening, ultrasonography, **amniocentesis**, and **chorionic villus sampling**.

Treatment

There is no cure for Edwards' syndrome. Since trisomy 18 babies frequently have major physical abnormalities, doctors and parents face difficult choices regarding treatment. Abnormalities can be treated to a certain degree with surgery, but extreme invasive procedures may not be in the best interests of an infant whose lifespan is measured in days or weeks. Medical therapy often consists of supportive care with

the goal of making the infant comfortable, rather than prolonging life.

Prognosis

Most children born with trisomy 18 die within their first year of life. The average lifespan is less than two months for 50% of the children, and 90–95% die before their first birthday. The 5–10% of children who survive their first year are severely intellectually disabled. They need support to walk, and learning is limited. Verbal communication is also limited, but they can learn to recognize and interact with others.

Prevention

Edwards' syndrome cannot be prevented.

Ehlers-Danlos syndrome

Definition

The Ehlers-Danlos syndromes (EDS) refer to a group of inherited disorders that affect collagen structure and function. Genetic abnormalities in the manufacturing of collagen within the body affect connective tissues, causing them to be abnormally weak.

Description

Collagen is a strong, fibrous protein that lends strength and elasticity to connective tissues such as the skin, tendons, organ walls, cartilage, and blood vessels. Each of these connective tissues requires collagen tailored to meet its specific purposes. The many roles of collagen are reflected in the number of genes dedicated to its production. There are at least 28 genes in humans that encode at least 19 different types of collagen. Mutations in these genes can affect basic construction as well as the fine-tuned processing of the collagen.

Elasticity of the skin is one characteristic of this rare disorder. *(© Biophoto Associates/Photo Researchers, Inc.)*

EDS was originally described by Dr. Van Meekeren in 1682. Dr. Ehlers and Dr. Danlos further characterized the disease in 1901 and 1908, respectively. According to the Ehlers-Danlos National Foundation, one in 5,000 to one in 10,000 people are affected by some form of EDS.

EDS is a group of genetic disorders that usually affects the skin, ligaments, joints, and blood vessels. Classification of EDS types was revised in 1997. The new classification involves categorizing the different forms of EDS into six major sub-types, including classical, hypermobility, vascular, kyphoscoliosis, arthrochalasia, and dermatosparaxis, and a collection of rare or poorly defined varieties. This new classification is simpler and based more on descriptions of the actual symptoms.

Classical type

Under the old classification system, EDS classical type was divided into two separate types: type I and type II. The major symptoms involved in EDS classical type are the skin and joints. The skin has a smooth, velvety texture and **bruises** easily. Affected individuals typically have extensive scaring, particularly at the knees, elbows, forehead, and chin. The joints are hyperextensible, giving a tendency towards dislocation of the hip, shoulder, elbow, knee, or clavicle. Due to decreased muscle tone, affected infants may experience a delay in reaching motor milestones. Children may have a tendency to develop

WWW.BOOKBAZ.IR

hernias or other organ shifts within the abdomen. Sprains and partial or complete joint dilocations are also common. Symptoms can range from mild to severe. EDS classical type is inherited in an autosomal dominant manner.

There are three major clinical diagnostic criteria for EDS classical type. These include skin hyperextensibility, unusually wide **scars**, and joint hypermobility. At this time there is no definitive test for the diagnosis of classical EDS. Both DNA and biochemical studies have been used to help identify affected individuals. In some cases, a **skin biopsy** has been found to be useful in confirming a diagnosis. Unfortunately, these tests are not sensitive enough to identify all individuals with classical EDS. If there are multiple affected individuals in a family, it may be possible to perform prenatal diagnosis using a DNA information technique known as a linkage study.

Hypermobility type

Excessively loose joints are the hallmark of this EDS type, formerly known as EDS type III. Both large joints, such as the elbows and knees, and small joints, such as toes and fingers, are affected. Partial and total joint **dislocations** are common, and particularly involve the jaw, knee, and shoulder. Many individuals experience chronic limb and joint **pain**, although x rays of these joints appear normal. The skin may also bruise easily. **Osteoarthritis** is a common occurrence in adults. EDS hypermobility type is inherited in an autosomal dominant manner.

There are two major clinical diagnostic criteria for EDS hypermobility type. These include skin involvement (either hyperextensible skin or smooth and velvety skin) and generalized joint hypermobility. At this time there is no test for this form of EDS.

Vascular type

Formerly called EDS type IV, EDS vascular type is the most severe form. The connective tissue in the intestines, arteries, uterus, and other hollow organs may be unusually weak, leading to organ or blood vessel rupture. Such ruptures are most likely between ages 20 and 40, although they can occur any time, and may be life-threatening.

There is a classic facial appearance associated with EDS vascular type. Affected individuals tend to have large eyes, a thin pinched nose, thin lips, and a slim body. The skin is thin and translucent, with veins dramatically visible, particularly across the chest.

The large joints have normal stability, but small joints in the hands and feet are loose, showing hyperextensibility. The skin bruises easily. Other complications may include collapsed lungs, premature **aging** of the skin on the hands and feet, and ruptured arteries and veins. After surgery there tends to be poor wound healing, a complication that tends to be frequent and severe. **Pregnancy** also carries the risk of complications. During and after pregnancy there is an increased risk of the uterus rupturing and of arterial bleeding. Due to the severe complications associated with EDS type IV, death usually occurs before the fifth decade. A study of 419 individuals with EDS vascular type, completed in 2000, found that the median survival rate was 48 years, with a range of 6–73 years. EDS vascular type is inherited in an autosomal dominant manner.

There are four major clinical diagnostic criteria for EDS vascular type. These include thin translucent skin, arterial/intestinal/uterine fragility or rupture, extensive bruising, and characteristic facial appearance. EDS vascular type is caused by a change in the gene COL3A1, which codes for one of the collagen chains used to build Collage type III. Laboratory testing is available for this form of EDS. A skin biopsy may be used to demonstrate the structurally abnormal collagen. This type of biochemical test identifies more than 95% of individuals with EDS vascular type. Laboratory testing is recommended for individuals with two or more of the major criteria.

DNA analysis may als be used to identify the change within the COL3A1 gene. This information may be helpful for **genetic counseling** purposes. Prenatal testing is available for pregnancies in which an affected parent has been identified and their DNA mutation is known or their biochemical defect has been demonstrated.

Kyphoscoliosis type

The major symptoms of kyphoscoliosis type, formerly called EDS type VI, are general joint looseness. At birth, the muscle tone is poor, and motor skill development is subsequently delayed. Also, infants with this type of EDS have an abnormal curvature of the spine (**scoliosis**). The scoliosis becomes progressively worse with age, with affected individuals usually unable to walk by age 20. The eyes and skin are fragile and easily damaged, and blood vessel involvement is a possibility. The bones may also be affected as demonstrated by a decrease in bone mass. Kyphoscoliosis type is inherited in an autosomal recessive manner.

There are four major clinical diagnostic criteria for EDS kyphoscoliosis type. These include generaly

loose joints, low muscle tone at birth, scoliosis at birth (which worsens with age), and a fragility of the eyes, which may give the white area of the eye a blue tint or cause the eye to rupture. This form of EDS is caused by a change in the PLOD gene on chromosome 1, which encodes the enzyme lysyl hydroxylase. A laboratory test is available in which urinary hydroxylysyl pryridinoline is measured. This test, performed on urine is extremely senstive and specific for EDS kyphoscolios type. Laboratory testing is recommended for infants with three or more of the major diagnostic criteria.

Prenatal testing is available if a pregnancy is known to be at risk and an identified affected family member has had positive laboratory testing. An **amniocentesis** may be performed in which fetal cells are removed from the amniotic fluid and enzyme activity is measured.

Arthrochalasia type

Dislocation of the hip joint typically accompanies arthrochalasia type EDS, formerly called EDS type VIIB. Other joints are also unusually loose, leading to recurrent partial and total dislocations. The skin has a high degree of stretchability and bruises easily. Individuals with this type of EDS may also experience mildly diminished bone mass, scoliosis, and poor muscle tone. Arthrochalasia type is inherited in an autosomal dominant manner.

There are two major clinical diagnostic criteria for EDS arthrochalasia type. These include severe generalized joing hypermobility and bilateral hip dislocation present at birth. This form of EDS is caused by a change in either of two components of Collage type I, called proa1(I) type A and proa2(I) type B. A skin biopsy may be preformed to demonstrate an abnormality in either components. Direct DNA testing is also available.

Dermatosparaxis type

Individuals with this type of EDS, once called type VIIC, have extremely fragile skin that bruises easily but does not scar excessively. The skin is soft and may sag, leading to an aged appearance even in young adults. Individuals may also experience hernias. Dermatosparaxis type is inherited in an autosomal recessive manner.

There are two major clinical diagnostic criteria for EDS dematosparaxis type. These include severe skin fragility and sagging or aged appearing skin. This form of EDS is caused by a change in the enzyme called procollagen I N-terminal peptidase. A skin biopsy may be preformed for a definitive diagnosis of Dermatosparaxis type.

Other types

There are several other forms of EDS that have not been as clearly defined as the aforementioned types. Forms of EDS within this category may present with soft, mildly stretchable skin, shortened bones, chronic **diarrhea**, joint hypermobility and dislocation, bladder rupture, or poor wound healing. Inheritance patterns within this group include X-linked recessive, autosomal dominant, and autosomal recessive.

Causes and symptoms

There are numerous types of EDS, all caused by changes in one of several genes. The manner in which EDS is inherited depends on the specific gene involved. There are three patterns of inheritance for EDS: autosomal dominant, autosomal recessive, and X-linked (extremely rare).

Chromosomes are made up of hundreds of small units known as genes, which contain the genetic material necessary for an individual to develop and function. Humans have 46 chromosomes, which are matched into 23 pairs. Because chromosomes are inherited in pairs, each individual receives two copies of each chromosome and likewise two copies of each gene.

Changes or mutations in genes can cause genetic diseases in several different ways, many of which are represented within the spectrum of EDS. In autosomal dominant EDS, only one copy of a specific gene must be changed for a person to have EDS. In autosomal recessive EDS, both copies of a specific gene must be changed for a person to have EDS. If only one copy of an autosomal recessive EDS gene is changed the person is referred to as a carrier, meaning they do not have any of the signs or symptoms of the disease itself, but carry the possibility of passing on the disorder to a future child. In X-linked EDS a specific gene on the X chromosome must be changed. However, this affects males and females differently because males and females have a different number of X chromosomes.

The few X-linked forms of EDS fall under the category of X-linked recessive. As with autosomal recessive, this implies that both copies of a specific gene must be changed for a person to be affected. However, because males only have one X-chromosome, they are affected if an X-linked recessive EDS gene is changed on their single X-chromosome. That is, they are affected even though they have only one changed copy. On the other hand, that same gene must

WWW.BOOKBAZ.IR

KEY TERMS

Arthrochalasia—Excessive loosness of the joints.

Blood vessels—General term for arteries, veins, and capillaries that transport blood throughout the body.

Cartilage—Supportive connective tissue that cushions bone at the joints or which connects muscle to bone.

Collagen—The main supportive protein of cartilage, connective tissue, tendon, skin, and bone.

Connective tissue—A group of tissues responsible for support throughout the body; includes cartilage, bone, fat, tissue underlying skin, and tissues that support organs, blood vessels, and nerves throughout the body.

Dermatosparaxis—Skin fragility caused by abnormal collagen.

Hernia—A rupture in the wall of a body cavity, through which an organ may protrude.

Homeopathic—A holistic and natural approach to healthcare.

Hyperextensibility—The ability to extend a joint beyond the normal range.

Hypermobility—Unusual flexibility of the joints, allowing them to be bent or moved beyond their normal range of motion.

Joint dislocation—The displacement of a bone.

Kyphoscoliosis—Abnormal front-to-back and side-to-side curvature of the spine.

Ligament—A type of connective tissue that connects bones or cartilage and provides support and strength to joints.

Osteoarthritis—A degenerative joint disease that causes pain and stiffness.

Scoliosis—An abnormal, side-to-side curvature of the spine.

Tendon—A strong connective tissue that connects muscle to bone.

Uterus—A muscular, hollow organ of the female reproductive tract. The uterus contains and nourishes the embryo and fetus from the time the fertilized egg is implanted until birth.

Vascular—Having to do with blood vessels.

be changed on both of the X-chromosomes in a female for her to be affected.

Although there is much information regarding the changes in genes that cause EDS and their various inheritance patterns, the exact gene mutation for all types of EDS is not known.

Diagnosis

Clinical symptoms such as extreme joint looseness and unusual skin qualities, along with family history, can lead to a diagnosis of EDS. Specific tests, such as skin biopsies are available for diagnosis of certain types of EDS, including vascular, arthrochalasia, and dermatosparaxis types. A skin biopsy involves removing a small sample of skin and examining its microscopic structure. A urine test is available for the Kyphoscoliosis type.

Management of all types of EDS may include genetic counseling to help the affected individual and their family understand the disorder and its impact on other family members and future children.

If a couple has had a child diagnosed with EDS the chance that they will have another child with the same disorder depends on with what form of EDS the child has been diagnosed and if either parent is affected by the same disease or not.

Individuals diagnosed with an autosomal dominant form of EDS have a 50% chance of passing the same disorder on to a child in each pregnancy. Individuals diagnosed with an autosomal recessive form of EDS have an extremely low risk of having a child with the same disorder.

X-linked recessive EDS is accompanied by a slightly more complicated pattern of inheritance. If a father with an X-linked recessive form of EDS passes a copy of his X chromosome to his children, the sons will be unaffected and the daughters will be carriers. If a mother is a carrier for an X-linked recessive form of EDS, she may have affected or unaffected sons, or carrier or unaffected daughters, depending on the second sex chromosome inherited from the father.

Prenatal diagnosis is available for specific forms of EDS, including kyphoscoliosis type and vascular type. However, prenatal testing is only a possibility in these types if the underlying defect has been found in another family member.

Treatment

Medical therapy relies on managing symptoms and trying to prevent further complications. There is no cure for EDS.

Braces may be prescribed to stabilize joints, although surgery is sometimes necessary to repair joint damage caused by repeated dislocations. **Physical therapy** teaches individuals how to strengthen muscles around joints and may help to prevent or limit damage. Elective surgery is discouraged due to the high possibility of complications.

Alternatives

There are anecdotal reports that large daily doses 0.04–0.14 oz (1–4 g) of vitamin C may help decrease bruising and aid in wound healing. Constitutional homeopathic treatment may be helpful in maintaining optimal health in persons with a diagnosis of EDS. An individual with EDS should discuss these types of therapies with their doctor before beginning them on their own. Therapy that does not require medical consultation involves protecting the skin with sunscreen and avoiding activities that place **stress** on the joints.

Prognosis

The outlook for individuals with EDS depends on the type of EDS with which they have been diagnosed. Symptoms vary in severity, even within one sub-type, and the frequency of complications changes on an individual basis. Some individuals have negligible symptoms while others are severely restricted in their daily life. Extreme joint instability and scoliosis may limit a person's mobility. Most individuals will have a normal lifespan. However, those with blood vessel involvement, particularly those with EDS vascular type, have an increased risk of fatal complications.

EDS is a lifelong condition. Affected individuals may face social obstacles related to their disease on a daily basis. Some people with EDS have reported living with fears of significant and painful skin ruptures, becoming pregnant (especially those with EDS vascular type), their condition worsening, becoming unemployed due to physical and emotional burdens, and social stigmatization in general.

Constant bruises, skin **wounds**, and trips to the hospital take their toll on both affected children and their parents. Prior to diagnosis parents of children with EDS have found themselves under suspicion of **child abuse**.

Some people with EDS are not diagnosed until well into adulthood and, in the case of EDS vascular type, occasionally not until after death due to complications of the disorder. Not only may the diagnosis itself be devastating to the family, but in many cases other family members find out for the first time they are at risk for being affected.

Although individuals with EDS face significant challenges, it is important to remember that each person is unique with their own distinguished qualities and potential. Persons with EDS go on to have families, to have careers, and to be accomplished citizens, surmounting the challenges of their disease.

Ehrlichiosis

Definition

Ehrlichiosis is a bacterial infection that is spread by ticks. Symptoms include **fever**, chills, **headache**, muscle aches, and tiredness.

Description

Ehrlichiosis is a tick-borne disease caused by infection with *Ehrlichia* bacteria. Ticks are small, blood-sucking arachnids. Although some ticks carry disease-causing organisms, most do not. When an animal or person is bitten by a tick that carries bacteria, the bacteria are passed to that person or animal during the tick's feeding process. It is believed that the tick must remain attached to the person or animal for at least 24 hours to spread the infection.

There are two forms of ehrlichiosis in the United States; human monocytic ehrlichiosis and human granulocytic ehrlichiosis. Monocytic ehrlichiosis is caused by *Ehrlichia chaffeensis*, which is spread by the Lone Star tick, *Amblyomma americanum*. About 600 cases of monocytic ehrlichiosis had been reported in 30 states, primarily in the southeastern and south central United

WWW.BOOKBAZ.IR

KEY TERMS

Tick-borne disease—A disease that is spread to animals by the bite of an infected tick.

States. The bacteria that causes granulocytic ehrlichiosis is not known, but suspected to be either *Ehrlichia equi* or *Ehrlichia phagocytophila*. Granulocytic ehrlichiosis is probably spread by the blacklegged tick *Ixodes scapularis* (which also spreads **Lyme disease**). About 100 cases of granulocytic ehrlichiosis have been reported in Connecticut, Massachusetts, Rhode Island, Minnesota, New York, and Wisconsin.

Causes and symptoms

Both forms of ehrlichiosis have similar symptoms, and the illnesses can range from mild to severe and life-threatening. Risk factors include old age and exposure to ticks through work or recreation. Symptoms occur seven to 21 days following a tick bite although patients may not recall being bitten. Fever, tiredness, headache, muscle aches, chills, loss of appetite, confusion, nausea, and **vomiting** are common to both diseases. A rash may occur.

Diagnosis

Ehrlichiosis may be diagnosed and treated by doctors who specialize in blood diseases (hematologists) or an **infectious disease** specialist. Because ehrlichiosis is not very common and the symptoms are not unique, it may be misdiagnosed. A recent history of a tick bite is helpful in the diagnosis. Blood tests will be done to look for antibodies to *Ehrlichia*. Staining and microscopic examination of the blood sample may show *Ehrlichia* bacteria inside white blood cells. Another test, called polymerase chain reaction (PCR), is a very sensitive assay to detect bacteria in the blood sample, but it is not always available.

Treatment

Antibiotic treatment should begin immediately if ehrlichiosis is suspected, even if laboratory results are not available. Treatment with either tetracycline (Sumycin, Achromycin V) or doxycycline (Monodox, Vibramycin) is recommended. Many patients with ehrlichiosis are admitted to the hospital for treatment.

Prognosis

For otherwise healthy people, a full recovery is expected following treatment for ehrlichiosis. Elderly patients are at a higher risk for severe disease, which may be fatal. Serious complications include lung or gastrointestinal bleeding. Two to 10 patients out of 100 die from the disease.

Prevention

The only prevention for ehrlichiosis is to minimize exposure to ticks by staying on the trail when walking through the woods, avoiding tall grasses, wearing long sleeves and tucking pant legs into socks, wearing insect repellent, and checking for ticks after an outing. Remove a tick as soon as possible by grasping the tick with tweezers and gently pulling.

Elder abuse

Definition

Elder **abuse** is a general term used to describe harmful acts toward an elderly adult, such as physical abuse, **sexual abuse**, emotional or psychological abuse, financial exploitation, and neglect, including self-neglect.

Description

Results from the National Elder Abuse Incidence Study, funded in part by the Administration on **Aging**, suggest that over 500,000 people 60 years of age and older are abused or neglected each year in the United States. It was also found that four times as many incidents of abuse, neglect, or self-neglect are never reported, causing researchers to estimate that as many as two million elderly persons in the United States are abused each year. In 90% of the cases, the abusers were found to be family members and most often were the adult children or spouses of those abused. In addition, equal numbers of men and women have been

identified as the abusers. However, women, especially those over 80 years of age, tend to be victimized more than men.

Elder abuse can take place anywhere, but the two main settings addressed by law are domestic settings, such as the elder's home or the caregiver's home, and institutional settings, such as a nursing home or group home. In general, there are five basic types of elderly abuse: physical, sexual, emotional or psychological, financial, and neglect. Data from National Center on Elder Abuse indicates that more than half of the cases reported involve some kind of neglect, whereas 1 in 7 cases involve physical abuse. It is considered neglect when a caretaker deprives an elderly person of the necessary care needed in order to avoid physical or mental harm. Sometimes the behavior of an elderly person threatens his or her own health; in those cases, the abuse is called self-neglect. Physical abuse refers to physical force that causes bodily harm to an elderly person, such as slapping, pushing, kicking, pinching, or burning.

About 1 in 8 cases of elderly abuse involve some form of financial exploitation, which is defined as the use of an elderly person's resources without his or her consent. The National Center on Elder Abuse defines emotional and psychological abuse of a senior as causing anguish, **pain**, or distress through verbal or nonverbal acts, such as verbal assaults, insults, intimidation, and humiliation, for example. Isolating elderly persons from their friends and family as well as giving them the silent treatment are two other forms of emotional and psychological abuse. Any kind of non-consensual sexual contact with an elderly person that takes place without his or her consent is considered sexual abuse.

Causes and symptoms

Elder abuse is a complex problem that can be caused by many factors. According to the National Center on Elder Abuse, social **isolation** and mental impairment are two factors of elder abuse. Studies show that people advanced in years, such as in their eighties, with a high level of frailty and dependency are more likely to be victims of elder abuse than people who are younger and better equipped to stand up for themselves. Because spouses make up a large percentage of elder abusers, at least 40% statistically, some research has been done in the area, which shows that a pattern of domestic violence is associated with many of the cases. The risk of elder abuse appears to be especially high when adult children live with their elderly parents for financial reasons or because they have personal problems, such as drug dependency or mental illness. Some experts have speculated that elderly people living in rural areas with their caretakers may have a higher risk of being abused than city dwellers. The idea behind this theory is that the opportunity exists for the abuse to occur, but there is less likelihood that the abuser will be caught. More research in this very important area is needed in order to illuminate the relationship between these factors.

The National Center on Elder Abuse identifies the following as signs of elder abuse:

- Bruises, pressure marks, broken bones, abrasions, and burns may indicate physical abuse or neglect.
- Unexplained withdrawal from normal activities and unusual depression may be indicators of emotional abuse.
- Bruises around the breasts or genital area, as well as unexplained bleeding around the genital area, may be signs of sexual abuse.
- Large withdrawals of money from an elder's bank account, sudden changes in a will, and the sudden disappearance of valuable items may be indications of financial exploitation.
- Bedsores, poor hygiene, unsanitary living conditions, and unattended medical needs may be signs of neglect.
- Failure to take necessary medicines, leaving a burning stove unattended, poor hygiene, confusion, unexplained weight loss, and dehydration may all be signs of self-neglect.

Diagnosis and treatment

The National Committee for the Prevention of Elder Abuse notes that Adult Protective Services (APS) caseworkers are often on the front lines when it comes to elderly abuse. People being abused or those who believe abuse is taking place can turn to their local APS office for help. The APS routinely screens calls, keeps all information confidential, and, if necessary, sends a caseworker out to conduct an investigation. In the event that a crisis intervention is needed, the APS caseworker can arrange for any necessary emergency treatment. If it is unclear whether elder abuse has taken place, the APS caseworker can serve as a liaison between the elderly person and other community agencies.

According to the National Committee for the Prevention of Elder Abuse, "professionals in the field of aging are often the first to discover signs of elder abuse." Providing encouragement and advice, they play a critical role in educating others with regard to the needs of the elderly. They not only provide valuable

WWW.BOOKBAZ.IR

support to the victims of abuse, but they also monitor high-risk situations and gather important information that can help validate that abuse has taken place.

Some people might think that a person who has cognitive impairment might be unable to describe mistreatment; however, that is not the case. In fact, guidelines set by the American Medical Association call for "routine questions about abuse and neglect even among patients with cognitive impairment in order to improve the identification of cases and implement appropriate treatment and referral." Rather than an inability to describe mistreatment, what might stop an elderly person from reporting abuse is a sense of embarrassment or fear of retaliation. To complicate matters, differences exist among cultural groups regarding what defines abuse.

Most states have established laws that define elder abuse and require health care providers to report any cases they encounter with penalties attached for failing to do so. Indeed, statistics show that health care providers, for example, report almost 25% of the known cases of elder abuse. Therefore, physicians play a very important role in identifying and treating elders who have been abused. And yet, in an article published by the *Journal of the American Geriatrics Society*, Dr. Conlin pointed out that only 1 of every 13 cases of elder abuse are reported by physicians. There may be several reasons for this. In some cases, the problem may simply go unnoticed, especially if the physician has no obvious reason to suspect any wrongdoing. In other cases, the patient may hide or deny the problem.

In recent years, much media attention has been focused on elderly abuse that takes place in institutional settings. Anyone who believes that a loved one is being abused while in a nursing home or other institutional setting should contact the authorities for assistance immediately.

Prognosis

The mortality rate of an elderly person who has been mistreated is higher than the mortality rate of an elderly person who has not experienced abuse. Nonetheless, numerous success stories exist regarding successful interventions. Social workers and health care professionals, as well as concerned citizens from a variety of backgrounds, have played a key role in identifying and obtaining treatment for abused elders.

Prevention

Planning for the future is one of the best ways to avoid elder abuse. Consider a variety of retirement options, ones that will encourage safety as well as independence. It is important to stay active in the community. Avoiding isolation minimizes the likelihood that abuse will occur. Seek professional counsel when necessary; it is important for everyone to know their rights and to be advocates on their own behalf.

Electric shock injuries

Definition

Electricity is a form of energy generated by the flow of electrons across a potential gradient from high to low concentration through a conductive material. Electrical injuries in humans are caused by contact with an electrical current, either natural lightning or mechanically generated.

Demographics

Electrical injuries were rare in industrialized societies until the 1870s and 1880s, when a series of inventions by Thomas Edison (1847–1931) and George Westinghouse (1846–1914) made it possible to transmit electricity over long-distance wires from one location to another for commercial and scientific purposes. The first fatal industrial accident involving an electric shock occurred in Lyon, France, in 1879.

Electrical injuries are responsible for about 1,000 deaths in the United States each year, or about 1% of all accidental deaths. About a quarter of these fatalities are caused by natural lightning. Electric shocks are responsible for 5% of all admissions to specialized burn treatment units in North America.

In the United States, 80% of all electrical injuries occur in adult men, largely because of occupational choices. Among children, the male: female ratio is 3:1. Low-voltage injuries are most common among toddlers; high-voltage injuries primarily affect risk-taking adolescents and adults in high-risk occupations.

According to the Bureau of Labor Statistics, electric shocks are the second leading cause of death in the construction industry in North America. With regard to injuries caused by contact with overhead powerlines, between 27% and 60% of cases resulted in over 31 days lost from work—compared to 18–20% for all other occupational injury and illness. Injuries caused by electric shocks are also costly to employers; a researcher at the Electric Power Research Institute in Palo Alto, California, estimates that the cost to American employers is approximately $15.75 million *per case* in direct and indirect costs.

Description

Accidental electrical injuries

Electrical injuries are classified according to three factors: power source (lightning or human-generated electricity); voltage (high or low); and type of current (alternating or direct). Each is associated with certain patterns of injury. Most electrical injuries are accidental.

The minimum current that humans can feel is 1 milliampere (abbreviated mA). An ampere, named for the French mathematician and physicist André-Marie Ampère (1775–1836), is a measure of the amount of electric charge passing a given point per unit time. One ampere represents 6.241 x 10^{18} electrons passing a given point in a wire in one second of time. In general, a current of 100 mA will be lethal if it passes through sensitive parts of the human body; a current as low as 60 mA can cause **ventricular fibrillation**, irregular contraction of the muscles in the two lower chambers of the heart.

Intentional use of electric shocks

Electric shocks have been used in medicine to treat mental illness, particularly depression (**electroconvulsive therapy** or ECT); to correct irregular heart rhythms (**defibrillation** and **cardioversion**); and to relieve **pain** by stimulating opioid receptors in the central nervous system (transcutaneous **electrical nerve stimulation** or TENS).

Electricity was used as a form of torture or punishment almost as soon as it was known to cause accidental workplace injuries. Since the 1930s, the Nazis and other tyrannical regimes used cattle prods and similar devices to torture people. The tasers currently used by some police departments are electroshock devices that cause strong involuntary contractions of the muscles controlling movement, thus temporarily incapacitating violent or intoxicated suspects.

Electrocution as a method of capital punishment was introduced in the late 1880s on the recommendation of a committee in New York State seeking a more humane method of execution than hanging. Thomas Edison recommended the use of alternating current to electrocute criminals, maintaining that it would cause instantaneous death. The first use of the electric chair in New York in 1890, however, was a disaster, requiring eight minutes to cause death. George Westinghouse is reported to have said that it would have been more humane to use an axe. As of 2015, only five states still use the electric chair as an option for execution.

Risk factors

Risk factors for electrical injuries include:

- Working or playing outside during an electrical storm.
- Employment in an occupation related to the generation of electricity or servicing of electrical equipment or power lines.
- Employment in the construction industry, mining, or public transportation.
- Natural disasters, including hurricanes, tornadoes, earthquakes, and ice storms, which bring down or disrupt high-voltage power lines.
- Theft of copper and other metals from construction sites and other areas close to high-voltage wires.

Causes and symptoms

Causes

Electricity damages the cells in human tissues in two basic ways: heating and blast force. The passage of electrical current through cell membranes causes their temperatures to rise, leading to disruption of the cell membrane itself (at 108°F [42°C]); denaturation of protein molecules in the cell (at 113°F [45°C]); and destruction of DNA (at 149°F [65°C] or higher). In most cases of high-voltage electrical shock, heat damage occurs immediately at contact points but requires 1–3 seconds to injure deeper tissues. The blast force of electric current can cause significant blunt **trauma** injuries.

The overall severity of electrical injury depends on the current's pressure (voltage), the amount of current (amperage), the type of current (direct vs. alternating), the body's resistance to the current, the current's path through the body, and how long the body remains in contact with the current. The interplay of these factors can produce effects ranging from barely noticeable tingling to instant death; every part of the body is vulnerable. Although the severity of

WWW.BOOKBAZ.IR

injury is determined primarily by the voltage, low voltage can be just as dangerous as high voltage under the right circumstances. People have been killed by shocks of just 50 volts. Electric voltage of 380 volts or less is considered low voltage. The United States national electric code defines high voltage as 600 volts or higher. High voltage is generated at power plants and is transformed down to approximately 120 volts for most wall outlets in homes.

Symptoms

Electric shocks can affect all the major organ systems in the human body. How electric shocks affect the skin is determined by the skin's resistance, which in turn is dependent upon the wetness, thickness, and cleanliness of the skin. Thin or wet skin is much less resistant than thick or dry skin. When skin resistance is low, the current may cause little or no skin damage but severely burn internal organs and tissues. Conversely, high skin resistance can produce severe skin **burns** but prevent the current from entering the body.

The nervous system (the brain, spinal cord, and nerves) is particularly vulnerable to injury. In fact, neurological problems are the most common kind of nonlethal harm suffered by electric shock victims. Some neurological damage is minor and clears up on its own or with medical treatment, but some is severe and permanent. Neurological problems may be apparent immediately after the accident, or gradually develop over a period of up to three years.

Damage to the respiratory and cardiovascular systems is most acute at the moment of injury. Electric shocks can paralyze the respiratory system or disrupt heart action, causing instant death. Also at risk are the smaller veins and arteries, which dissipate heat less easily than the larger blood vessels and can develop **blood clots**. Damage to the smaller vessels is probably one reason why **amputation** is often required following high-voltage injuries.

Many other sorts of injuries are possible after an electric shock, including **cataracts**, kidney failure, and substantial destruction of muscle tissue. The victim may fall or be hit by debris from exploding equipment. An electric arc flash may set clothing or nearby flammable substances on fire. Arc flashes can produce light intense enough to cause permanent blindness as well as heat intense enough (5,000–7,000°F [2,760–3,871°C]) to melt bone and vaporize the surfaces of nearby human beings and other objects. Strong shocks are often accompanied by violent **muscle spasms** that can break and dislocate bones. These spasms can also freeze the victim in place and prevent him or her from breaking away from the source of the current. Alternating current is considered three times as dangerous as direct current for this reason: high-voltage DC tends to cause one strong muscle spasm that throws the victim away from the source, whereas the cyclical flow of electrons in AC of the same voltage causes **paralysis** of the muscles that holds the victim in contact with the current.

Diagnosis

Diagnosis relies on gathering information about the circumstances of the accident, a thorough **physical examination**, and monitoring of cardiovascular and kidney activity. When at all possible, witnesses of the accident should be questioned about the circumstances of the event, particularly if the victim has lost consciousness or normal mental status. The victim's neurological condition can fluctuate rapidly and requires close observation. A computed tomography scan (CT scan) or **magnetic resonance imaging** (MRI) may be necessary to check for brain injury. Blood and urine samples may be taken. In some cases, the doctor may make a trial incision into burned muscle to assess the extent of tissue damage. The tissue sample is frozen and examined under a microscope to see whether the muscle tissue is still viable. If an arm or leg damaged by electricity is determined not to be viable, immediate amputation is necessary.

Treatment

Treatment of an electrical injury usually begins at the scene, although first responders will generally take the victim to an emergency department or specialized burn or trauma center as soon as possible. The victim of a severe electrical injury may be examined and treated by a variety of specialists, including emergency physicians, plastic surgeons, neurologists, ophthalmologists, and orthopedic surgeons.

Traditional

When an electric shock accident happens at home or in the workplace, the main power should immediately be shut off and 911 should be called. If that cannot be done, and current is still flowing through the victim, the alternative is to stand on a dry, nonconducting surface such as a folded newspaper, flattened cardboard carton, or plastic or rubber mat and use a nonconducting object such as a wooden broomstick (never a damp or metallic object) to push the

KEY TERMS

Alternating current (AC)—An electric current in which the flow of the electric charge periodically reverses direction. AC is the form in which electricity is usually delivered to homes. The usual household wall outlet (120 volts) provides a current with 120 reversals of the direction of flow occurring each second and is termed 60-cycle alternating current.

Amperage—A measurement of the amount of electric charge passing a given point per unit time. One ampere represents about 6.241×10^{18} electrons passing a given point in a wire in one second of time.

Antibiotics—Substances used against microorganisms that cause infection.

Arc flash—A type of electrical explosion resulting from electrical breakdown of the gases in air, which normally does not conduct electricity. Arc flashes can occur where there is sufficient voltage in an electrical system and a path to the ground or to lower voltage.

Cataract—Clouding of the lens of the eye or its capsule (surrounding membrane).

Computed tomography scan (CT scan)—A process that uses x rays to create three-dimensional images of structures inside the body.

Direct current (DC)—An electric current in which the electric charge moves in only one direction. It is the type of current produced by batteries and solar cells.

Electrolytes—Substances that conduct electric current within the body and are essential for sustaining life.

Magnetic resonance imaging (MRI)—The use of electromagnetic energy to create images of structures inside the body.

Skin grafting—A technique in which a piece of healthy skin from the patient's body (or a donor's) is used to cover another part of the patient's body that has lost its skin.

Taser—Also called a conducted electrical weapon or CEW, a taser is an electroshock device used by some police departments in various countries to subdue armed or otherwise dangerous suspects without having to use lethal force. Tasers work by interfering with the suspect's capacity to control voluntary muscles. The name *taser* is an acronym for *Thomas A. Swift's Electric Rifle*, an adventure novel about a fictional weapon published in 1911.

Voltage—The force necessary to drive an electric current between two specified points. A large voltage exerts a greater force, which moves more electrons through a wire at a given rate of time.

victim away from the source of the current. The victim and the source of the current must not be touched while the current is still flowing, for this contact can electrocute the rescuer. Emergency medical help should be summoned as quickly as possible. Trained electricians must use lineman's gloves to separate the victim from the circuit by a specially insulated pole. Looping a polydacron rope around the injured patient is another method of pulling him or her from the electric power source. Ideally, the electrician or first responder should stand on a dry surface during the rescue. People who are trained to perform **cardiopulmonary resuscitation** (CPR) should, if appropriate, begin **first aid** while waiting for emergency medical help to arrive.

Burn victims usually require treatment at a specialized burn center. Fluid replacement therapy is necessary to restore lost fluids and electrolytes. Severely injured tissue is repaired surgically, which can involve **skin grafting** or amputation. **Antibiotics** and antibacterial creams are used to prevent infection. Victims may also require treatment for kidney failure. Following surgery, **physical therapy** to facilitate recovery, and psychological counseling to cope with disfigurement, may be necessary.

Prognosis

The mortality rate for electrical injuries in the United States is approximately 3–5%. Many survivors, however, require amputation or are permanently disfigured by their burns. **Anxiety disorders** are common in survivors of high-voltage electrical injuries. About 73% of pregnant women injured by lightning or high-voltage electricity lose the baby. Injuries from household appliances and other low-voltage sources are less likely to produce extreme damage.

WWW.BOOKBAZ.IR

Prevention

Prevention of electrical injuries in the home or workplace begins with age-appropriate education about the nature of electricity and the importance of safety measures. The National Safety Council in the United States and Hydro-Québec (a power company) in Canada have handouts, videos, quizzes, and fact sheets about electrical safety on their websites (http://www.nsc.org/ and http://www.hydroquebec.com/security/index.html). These materials are written for the general public and are intended to help people recognize dangerous situations and take steps to protect themselves and their families before an electrical accident occurs.

People who are employed in workplaces with high-voltage electrical equipment or whose jobs require working with electricity should follow all safety precautions recommended by the National Safety Council:

- Those working near high-voltage lines should wear Class B helmets, which are designed to withstand 20,000 volts of AC for 3 minutes.
- Special insulated gloves should be worn, either Class 2 (provides protection against 20,000 volts) or Class 4 (protection against 40,000 volts), along with tinted eyewear to protect the eyes against arc flashes.
- Only employees with special training and authorization should work on high-voltage lines or equipment; other workers should not try to perform tasks for which they are not qualified or trained.
- Rubber-soled shoes or work boots must be worn on damp or wet surfaces.
- Workers should check that circuits, wiring, insulation, equipment, and cords or extension cords are in good repair.
- Hazards of any kind, including water or spills as well as damaged or defective equipment, should be reported to supervisors at once.

Parents and other adults need to be alert to possible electric dangers in the home. Damaged electric appliances, wiring, cords, and plugs should be repaired or replaced. Electrical repairs should be attempted only by people with the proper training. Hair dryers, radios, and other electric appliances should never be used in the bathroom or anywhere else they might accidentally come in contact with water. Young children need to be kept away from electric appliances and should be taught about the dangers of electricity as soon as they are old enough. Electric outlets require safety covers in homes with young children.

People should be particularly careful when using metal ladders outside or when installing outdoor television or CB radio base antennas, as accidental contact with an overhead power line can be fatal. In the late 1970s, there were about 100 deaths each year in the United States involving amateur installation of outdoor antennas.

During thunderstorms, people should go indoors immediately, even if no rain is falling, and boaters should return to shore as rapidly as possible. People who cannot reach indoor shelter should move away from such metallic objects as golf clubs and fishing rods and lie down in low-ground areas. Standing or lying under or next to tall or metallic structures is unsafe. An automobile is appropriate cover, as long as the radio is off. Telephones, computers, hair dryers, and other appliances that can act as conduits for lightning should not be used during thunderstorms.

Electrical nerve stimulation

Definition

Electrical nerve stimulation, also called transcutaneous electrical nerve stimulation (TENS), is a non-invasive, drug-free **pain management** technique. By sending electrical signals to underlying nerves, the battery-powered TENS device can relieve a wide range of chronic and acute **pain**.

Purpose

TENS is used to relieve pain caused by a variety of chronic conditions, including:

- neck and lower back pain
- headache/migraine
- arthritis
- post-herpetic neuralgia (lingering chronic pain after an attack of shingles)
- sciatica (pain radiating from lower back, through the legs, to the foot)
- temporomandibular joint pain
- osteoarthritis
- amputation (phantom limb)
- fibromyalgia (a condition causing aching and stiffness throughout the body)

The device is also effective against short-term pain, such as:

- shingles (painful skin eruptions along the nerves)
- bursitis (inflammation of tissue surrounding a joint)
- childbirth
- post-surgical pain
- fractures
- muscle and joint pain
- sports injuries
- menstrual cramps

Precautions

Because TENS may interfere with pacemaker function, patients with **pacemakers** should consult a cardiologist before using a TENS unit. Patients should also avoid electrical stimulation in the front of the neck, which can be hazardous. The safety of the device during **pregnancy** has not been established.

TENS does not cure any condition; it simply eases pain. Patients who are not sure what is causing their pain should consult a physician before using TENS.

WWW.BOOKBAZ.IR

KEY TERMS

Fibromyalgia—A condition characterized by aching and stiffness, fatigue and poor sleep, as well as tenderness at various sites on the body.

Osteoarthritis—A painful joint disease aggravated by mechanical stress.

Phantom limb—The perception that a limb is present (and throbbing with pain) after it has been amputated.

Post-herpetic neuralgia—Lingering pain that can last for years after an attack of shingles.

Sciatica—Pain that radiates along the sciatic nerve, extending from the buttock down the leg to the foot.

Temporomandibular joint pain (TMJ)—Pain and other symptoms affecting the head, jaw, and face that are caused when the jaw joints and muscles controlling them don't work together correctly.

Description

The TENS device is a small battery-powered stimulator that produces low-intensity electrical signals through electrodes on or near a painful area, producing a tingling sensation that reduces pain. There is no dosage limitation, and the patient controls the amount of pain relief.

Some experts believe TENS works by blocking pain signals in the spinal cord, or by delivering electrical impulses to underlying nerve fibers that lessen the experience of pain. Others suspect that the electrical stimulation triggers the release of natural painkillers in the body.

Patients can rent a TENS unit before buying one, to see if it is effective against their pain.

Preparation

After TENS has been prescribed, a doctor will refer the patient to a TENS specialist, who will explain how to use the machine. The specialist works with the patient to determine the settings and electrode placements for the best pain relief.

Risks

TENS is nonaddictive and completely safe. The only side effect may be a slight skin irritation or redness in some people, which can be prevented by using different gels or electrodes.

Results

The amount of relief a person gets using TENS depends on the underlying cause of the pain, a person's mental state, and whether or not medication is also used. At least one study found that both a real TENS machine and a placebo were equally effective in reducing pain. This suggests that at least part of its effectiveness may be due to the patient's belief in its ability to ease pain.

Carol A. Turkington

Electrical stimulation of the brain

Definition

Electrical stimulation of the brain (ESB) is a relatively new technique used to treat chronic **pain** and **tremors** associated with Parkinson's disease. ESB is administered by passing an electrical current through an electrode implanted in the brain.

Purpose

While the implantation of electrodes in the brain is used to treat or diagnose several disorders, the term ESB is limited here to the treatment of tremors, and as a **pain management** tool for patients suffering from back problems and other chronic injuries and illnesses.

Precautions

An ESB tremor control device, used in treating **Parkinson's** patients, may interfere with or be affected by cardiac **pacemakers** and other medical equipment. As a result, patients with other implanted medical equipment may not be good candidates for the therapy.

Description

Electrical stimulation of the brain, or deep brain stimulation, is effective in treating tremor in up to 88% of **Parkinson's** disease patients. An electrode is implanted into the thalamus (part of the brain) of the patient, and attached to an electric pulse generator via an extension wire. The pulse generator is implanted into the patient's pectoral, or chest area, and the extension wire is tunneled under the skin. The pulse generator sends out intermittent electrical stimulation

KEY TERMS

Infarction—A sudden insuffiency of local blood supply.

Neuralgia—Pain extending along one or more nerves.

Neuropathy—A functional disturbance or change in the nervous system.

Parkinson's disease—A chronic neurological illness that causes tremors, stiffness, and difficulty in moving and walking.

to the electrode in the thalamus, which inhibits or partially relieves the tremor. The generator can be turned on and off with a magnet, and needs to be replaced every three to five years.

Similar methods have been used to treat chronic pain that responded unfavorably to conventional therapies. A remote transmitter allows these patients to trigger electric stimulation to relieve their symptoms on an as-needed basis. Patients with failed back syndrome, trigeminal neuropathy (pertaining to the fifth cranial nerve), and **peripheral neuropathy** fared well for pain control with this treatment, while patients with **spinal cord injury** and postherpetic neuralagia (pain along the nerves following herpes) did poorly.

Preparation

The patient should be free of any type of infection before undergoing an ESB procedure. He or she may be advised to discontinue any medication for a prescribed period of time before surgery.

Aftercare

After **neurosurgery**, patients should undergo regular head dressing changes, minimize exposure to others, and practice good personal hygiene in order to prevent a brain infection. The head may also be kept elevated for a prescribed period of time in order to decrease swelling of the brain.

Risks

The implantation of electrodes into the brain carries risks of hemorrhage, infarction, infection, and cerebral **edema**. These complications could cause irreversible neurological damage.

Patients with an implanted ESB tremor control device may experience headaches, disequilibrium (a disturbance of the sense of balance), burning or tingling of the skin, or partial **paralysis**.

Results

ESB is effective in pain control for specific conditions. It can provide long-term pain relief with few side effects or complications.

For the control of tremors a deep brain stimulator does provide some relief. It is recommended for patients with tremors severe enough to affect their quality of life.

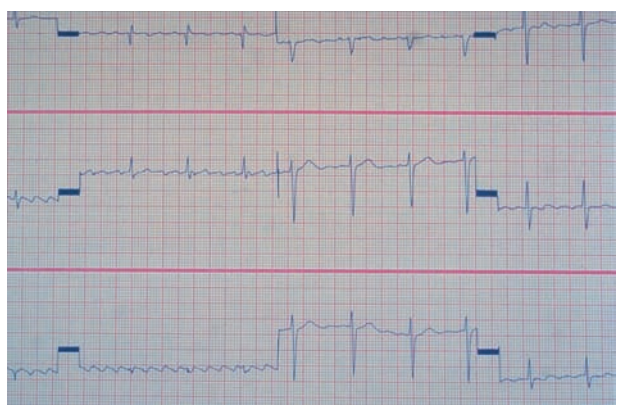
Electrocardiography

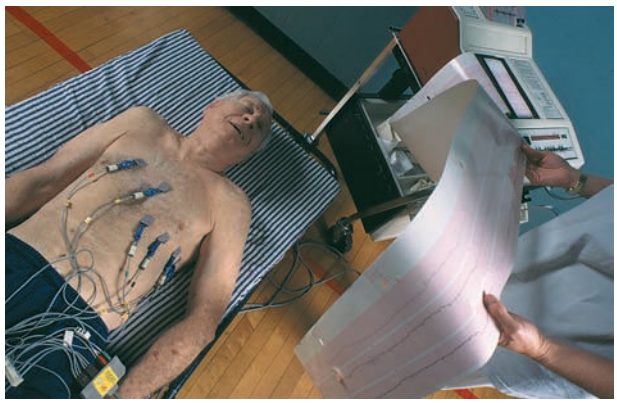
Definition

Electrocardiography is a commonly used, noninvasive procedure for recording electrical changes in the heart. The record, which is called an electrocardiogram (ECG or EKG), shows the series of waves that relate to the electrical impulses that occur during each beat of the heart. The results are printed on paper and/or displayed on a monitor to provide a visual



An EKG strip indicating atrial flutter. *(Custom Medical Stock Photo, Inc.)*

WWW.BOOKBAZ.IR



A patient undergoing electrocardiography. *(Russell Curtis/ Photo Researchers, Inc.)*

representation of heart function. The waves in a normal record are named P, Q, R, S, and T, and follow in alphabetical order. The number of waves may vary, and other waves may be present.

Purpose

Electrocardiography is a starting point for detecting many cardiac problems, including **angina** pectoris, stable angina, ischemic **heart disease**, **arrhythmias** (irregular heartbeat), tachycardia (fast heartbeat), bradycardia (slow heartbeat), myocardial infarction (**heart attack**), and certain congenital heart conditions. It is used routinely in physical examinations and for monitoring a patient's condition during and after surgery, as well as in the intensive care setting. It is the basic measurement used in exercise tolerance tests (**stress** tests) and is also used to evaluate symptoms such as chest **pain**, **shortness of breath**, and **palpitations**.

Demographics

According to the U.S. Centers for Disease Control (CDC), nearly 23 million EKG procedures were performed in doctor's offices in the year 2000.

Men are more likely to experience heart attacks than women, although a woman's risk of heart attack rises after **menopause**. African Americans, Hispanics, and Native Americans are all at greater risk for cardiovascular disease than Caucasians, in part because of the higher incidence of **diabetes mellitus** (a major risk factor for cardiovascular disease) in these populations.

Description

The electrocardiograph is conducted by a fully trained technologist and may be done in the cardiologist's office, a testing facility, or at a hospital patient's bedside. The technologist, or perhaps a nurse or nurse practitioner, will take the patient's medical history, educate them about the procedure they are about to undergo, and help them relax. The results of the electrocardiograph will be interpreted by a qualified physician, usually a cardiologist.

The patient disrobes from the waist up, and electrodes (tiny wires in adhesive pads) are applied to specific sites on the arms, legs, and chest. When attached, these electrodes are called leads; 3–12 leads may be employed for the procedure.

Muscle movement may interfere with the recording, which lasts for several beats of the heart. In cases where rhythm disturbances are suspected to be infrequent, the patient may wear a small Holter monitor in order to record continuously over a 24-hour period. This is known as ambulatory monitoring.

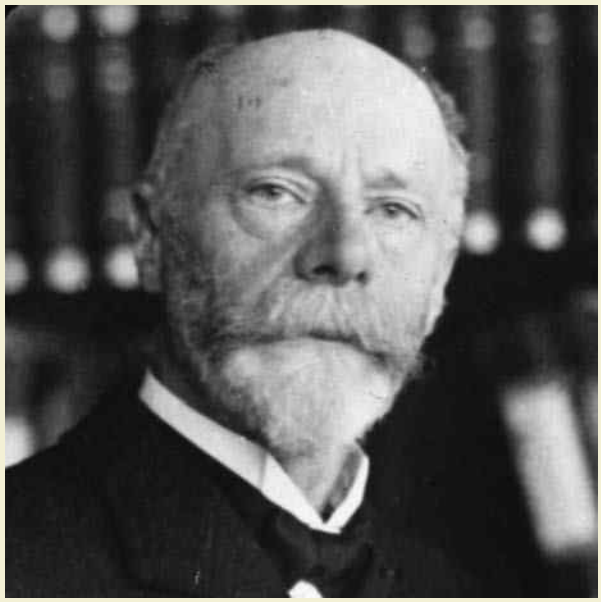
Special training is required for interpretation of the electrocardiogram. To summarize in the simplest manner the features used in interpretations, the P wave of the electrocardiogram is associated with the contraction of the atria—the two chambers of the heart that receive blood from the veins. The QRS series of waves, or QRS complex, is associated with ventricular contraction, with the T wave coming after the contraction. The ventricles are the two chambers of the heart that receive blood from the atria and send the blood into the arteries. Finally, the P-Q or P-R interval gives a value for the time taken for the electrical impulse to travel from the atria to the ventricle (normally less than 0.2 seconds).

Diagnosis

Heart problems are diagnosed by the pattern of electrical waves produced during the EKG, and an abnormal rhythm can be called dysrhythmia. The cause of dysrhythmia is ectopic beats. Ectopic beats are premature heartbeats that arise from a site other than the sinus node—commonly from the atria, atrioventricular node, or the ventricle. When these dysrhythmias are only occasional, they may produce no symptoms or simply a feeling that the heart is turning over or "flip-flopping." These occasional dysrhythmias are common in healthy people, but they also can be an indication of heart disease.

The varied sources of dysrhythmias provide a wide range of alterations in the form of the electrocardiogram. Ectopic beats display an abnormal QRS complex. This can indicate disease associated with insufficient blood supply to the heart muscle (myocardial ischemia). Multiple ectopic sites lead to rapid and

WILLEM EINTHOVEN (1860–1927)



Willem Einthoven. *(Getty Images.)*

Dutch researcher and physician Willem Einthoven (1860–1927) developed the first clinically applicable electrocardiogram.

Willem Einthoven was the first son in a family of six children. He was born on the island of Java in the area then known as the Dutch East Indies that today is Indonesia. His father, a physician in the army, died when Einthoven was six, and at ten he moved with his family from the East Indies to Utrecht in the Netherlands.

In the Netherlands, Einthoven attended medical school and initially was interested in ophthalmology. He went on to study various subjects, including anatomy, physiology, optics, acoustics, and physics. He obtained a faculty position in physiology at the University of Leiden, where he worked for most of his life.

The area for which Einthoven became best known was his effort in developing a method that would allow doctors to record the electrical activity of the human heart. He began with work that had been done by Augustus Waller (1856–1922). In 1887, Waller had used a mercury capillary electrometer to record the contractions of a human heart in a live patient. This was an enormous breakthrough, as previously there was little doctors could do to diagnose problems of the heart beyond examining explicit symptoms and listening to the heart through the chest. Waller's advance allowed physicians to more accurately represent the contractions of the heart.

As Einthoven began exploring and replicating Waller's work, he noticed some problems with the capillary electrometer technique. Einthoven found that the inertia of the electrometer produced mathematical errors that required complex corrections. Einthoven sought a more accurate way of measuring the electric activity of the heart.

Einthoven spent three years developing a string galvanometer, an instrument that detects electric current. The basic principle on which the string galvanometer is based was already in use, but Einthoven was the first to translate the principle into a method and machine that could be used by clinicians to investigate the heart. He developed a recording system using three limb leads, which remained a standard into the twenty-first century. Einthoven attached leads to the patient, and the electric current from the patient deflected a quartz string that was coated in silver. The movement of the string was then caught on photographic film, which could be developed to show a visual representation of the electric activity of the patient's heart. Einthoven published a paper outlining his methods in 1901.

After developing the necessary technology, Einthoven spent many years recording and analyzing the resulting patterns for individuals with healthy hearts and those with heart disease. He is credited with coining the term *electrocardiogram* and in 1924 was awarded the Nobel Prize in Physiology or Medicine for his work. Through subsequent decades, the equipment changed drastically; however, Einthoven's breakthrough has remained the essential technique that is the basis of all electrocardiography.

uncoordinated contractions of the atria or ventricles. This condition is known as fibrillation. When the atrial impulse fails to reach the ventricle, a condition known as **heart block** results.

Preparation

Patients are asked not to eat for several hours before a **stress test**. Before the leads are attached, the skin is cleaned to obtain good electrical contact at the electrode positions and, occasionally, shaving the chest may be necessary.

Aftercare

To avoid skin irritation from the salty gel used to obtain good electrical contact, the skin should be thoroughly cleaned after removal of the electrodes.

WWW.BOOKBAZ.IR

KEY TERMS

Ambulatory monitoring—ECG recording over a prolonged period during which the patient can move around.

Arrhythmia or dysrhythmia—Abnormal rhythm in hearts that contract in an irregular way.

ECG or EKG—A record of the waves that relate to the electrical impulses produced at each beat of the heart.

Ectopic beat—Abnormal heart beat arising elsewhere than from the sinoatrial node.

Electrodes—Tiny wires in adhesive pads that are applied to the body for EKG measurement.

Fibrillation—Rapid, uncoordinated contractions of the upper or the lower chambers of the heart.

Lead—Name given the electrode when it is attached to the skin.

Reperfusion therapy—Restoration of blood flow to an organ or tissue; following a heart attack, quickly opening blocked arteries to reperfuse the heart muscles to minimize damage.

Risks

The EKG is a noninvasive procedure that is virtually risk-free for the patient. There is a slight risk of heart attack for individuals undergoing a stress test EKG, but patients are carefully screened for their suitability for this test before it is prescribed.

Risk factors for heart disease include **obesity**, **hypertension** (high blood pressure), high **triglycerides** and total blood **cholesterol**, low HDL ("good") cholesterol, tobacco **smoking**, and increased age. People who have diabetes mellitus (either type 1 or type 2) are also at increased risk for cardiovascular disease.

Results

When the heart is operating normally, each part contracts in a specific order. Contraction of the muscle is triggered by an electrical impulse. These electrical impulses travel through specialized cells that form a conduction system. Following this pathway ensures that contractions will occur in a coordinated manner.

When the presence of all waves is observed in the electrocardiogram, and these waves follow the order defined alphabetically, the heart is said to show a normal sinus rhythm, and impulses may be assumed to be following the regular conduction pathway.

In the normal heart, electrical impulses—at a rate of 60–100 times per minute—originate in the sinus node. The sinus node is located in the first chamber of the heart, known as the right atrium, where blood reenters the heart after circulating through the body. After traveling down to the junction between the upper and lower chambers, the signal stimulates the atrioventricular node. From here, after a delay, it passes by specialized routes through the lower chambers or ventricles. In many disease states, the passage of the electrical impulse can be interrupted in a variety of ways, causing the heart to perform less efficiently.

The heart is described as showing arrhythmia or dysrhythmia when time intervals between waves or the order or the number of waves do not fit the normal pattern. Other features that may be altered include the direction of wave deflection and wave widths.

Alternatives

Electrocardiography is the gold standard for detecting heart conditions involving irregularities in electrical conduction and rhythm. Other tests that may be used in conjunction with an EKG include an echocardiogram (a sonogram of the heart's pumping action) and a stress test—an EKG that is done in conjunction with treadmill or other supervised exercise to observe the heart's function under stress.

Electroconvulsive therapy

Definition

Electroconvulsive therapy (ECT) is a medical treatment for severe mental illness in which a small, carefully controlled amount of electricity is introduced into the brain. This electrical stimulation, used in conjunction with **anesthesia** and muscle relaxant medications, produces a mild generalized seizure or convulsion. While used to treat a variety of psychiatric disorders, it is most effective in the treatment of severe depression, and provides the most rapid relief currently available for this illness.

Purpose

The purpose of electroconvulsive therapy is to provide relief from the signs and symptoms of mental illnesses such as severe depression, **mania**, and **schizophrenia**. ECT is indicated when patients need rapid improvement because they are suicidal, self-injurious, refuse to eat or drink, cannot or will not take medication as prescribed, or present some other danger to themselves. Antidepressant medications, while effective in many cases, may take two–six weeks to produce a therapeutic effect. Antipsychotic medications used to treat mania and schizophrenia have many uncomfortable and sometimes dangerous side effects, limiting their use. In addition, some patients develop **allergies** and are unable to take their medicine.

Precautions

The most common risks associated with ECT are disturbances in heart rhythm. Broken or dislocated bones occur very rarely.

Description

The treatment of severe mental illness, such as schizophrenia, using electroconvulsive therapy was introduced in 1938 by two Italian doctors named Cerletti and Bini. In those days many doctors believed that convulsions were incompatible with schizophrenia since, according to their obervations, this disease rarely occurred in individuals with **epilepsy**. They concluded, therefore, that if convulsions could be artifically produced in patients with schizophrenia, the illness could be cured. Some doctors were already using a variety of chemicals to produce seizures, but many of their patients died or suffered severe injuries because the strength of the convulsions could not be well controlled.

Electroconvulsive therapy is among the most controversial of all procedures used to treat mental illness. When it was first introduced, many people were frightened simply because it was called "shock treatment." Many assumed the procedure would be painful, others thought it was a form of electrocution, and still others believed it would cause brain damage. Unfortunately, unfavorable publicity in newspapers, magazines, and movies added to these fears.

Indeed, in those early years, patients and families were rarely educated by doctors and nurses regarding this or other forms of psychiatric treatment. In addition, no anesthesia or **muscle relaxants** were used. As a result, patients had violent seizures, and even though they did not remember them, the procedure itself was frightening.

The way these treatments are given today is very different from the procedures used in the past. Currently, ECT is offered on both an inpatient and outpatient basis. Hospitals have specially equipped rooms with oxygen, suction, and **cardiopulmonary resuscitation** (CPR) in order to deal with the rare emergency.

The treatment is carried out as follows: approximately 30 minutes before the scheduled treatment time, the patient may receive an injection of a medication (such as atropine) that keeps the pulse rate from decreasing too much during the convulsion. Next, the patient is placed on a cot and hooked up to a machine

WWW.BOOKBAZ.IR

that automatically takes and displays vital signs (temperature, pulse, respiration, and blood pressure) on a television-like monitor. A mild anesthetic is then injected into a vein, followed by a medication (such a Anectine) that relaxes all of the muscles in the body so that the seizure is mild, and the risk of broken bones is virtually eliminated.

When the patient is both relaxed and asleep, an airway is placed in the mouth to aid with breathing. Electrodes are placed on the sides of the head in the temple areas. An electric current is passed through the brain by means of a machine specifically designed for this purpose. The usual dose of electricity is 70–150 volts for 0.1–0.5 seconds. In the first stage of the seizure (tonic phase), the muscles in the body that have not been paralyzed by medication contract for a period of 5–15 seconds. This is followed by the second stage (clonic phase) that is characterized by twitching movements, usually visible only in the toes or in a non-paralyzed arm or leg. These are caused by alternating contraction and relaxation of these same muscles. This stage lasts approximately 10–60 seconds. The entire procedure, from beginning to end, lasts about 30 minutes.

The total number of treatments a patient will receive depends upon many factors such as age, diagnosis, the history of illness, family support, and response to therapy. Patients with depression, for example, usually require six to 12 treatments. Treatments are usually administered every other day, three times a week.

The electrodes may be placed on both sides of the head (bilateral) or one side (unilateral). While bilateral ECT appears to be somewhat more effective, unilateral ECT is preferred for individuals who experience prolonged confusion or forgetfulness following treatment. Many doctors begin treatment with unilateral ECT, then change to bilateral if the patient is not improving.

Post-treatment confusion and forgetfulness are common, though disturbing symptoms associated with ECT. Doctors and nurses must be patient and supportive by providing patients with factual information about recovery. Elderly patients, for example, may become increasingly confused and forgetful as the treatments continue. These symptoms usually subside with time, but a small minority of patients state that they have never fully recovered from these effects.

With the introduction of antipsychotics in the 1950s, the use of ECT became less frequent. These new medications provided relief for untold thousands of patients who suffered greatly from their illness. However, there are a number of side effects associated with these drugs, some of which are irreversible. Another drawback is that some medications do not produce a therapeutic effect for two–six weeks. During this time the patient may present a danger to himself or others. In addition, there are patients who do not respond to medicine or who have severe allergic reactions. For these individuals, ECT may be the only treatment that will help.

Preparation

Patients and relatives are prepared for ECT by being shown video tapes that explain both the procedure and the risks involved. The physician then answers any questions these individuals may have, and the patient is asked to sign an "Informed Consent Form." This gives the doctor and the hospital permission to administer the treatment.

Once the form is signed, the doctor performs a complete **physical examination**, and orders a number of tests that can help identify any potential problem. These tests may include a chest x ray, an electrocardiogram (ECG), **urinalysis**, spinal x ray, brain wave (EEG), and **complete blood count** (CBC).

Some medications, such as lithium and a type of antidepressant known as **monoamine oxidase inhibitors**, should be discontinued for some time before treatment. Patients are instructed not to eat or drink for at least eight hours prior to the procedure in order to reduce the possibility of **vomiting** and **choking**.

Aftercare

After the treatment, patients are moved to a recovery area. Vital signs are recorded every five minutes until the patient is fully awake, which may take 15–30 minutes. Some initial confusion may be present but usually disappears in a matter of minutes. There may be complaints of **headache**, muscle **pain**, or back pain. Such discomfort is quickly relieved by mild medications such as **aspirin**.

Risks

Advanced medical technology has substantially reduced the complications associated with ECT. These include slow heart beat (bradycardia), rapid heart beat (tachycardia), **memory loss**, and confusion. Persons at high risk for ECT include those with recent

KEY TERMS

Mania—A mood disorder in which a person experiences prolonged elation or irritability characterized by overactivity that can lead to exhaustion and medical emergencies.

Relapse—A return of the signs and symptoms of an illness.

Schizophrenia—A severe mental illness in which a person has difficulty distinguishing what is real from what is not real. It is often characterized by hallucinations, delusions, and withdrawal from people and social activities.

heart attack, uncontrolled blood pressure, brain tumors, and previous spinal injuries.

Results

ECT often produces dramatic improvement in the signs and symptoms of major depression, especially in elderly individuals, sometimes during the first week of treatment. While it is estimated that 50% of these patients will experience a future return of symptoms, the prognosis for each episode of illness is good. Mania also often responds well to treatment. The picture is not as bright for schizophrenia, which is more difficult to treat and is characterized by frequent relapses.

A few patients are placed on maintenance ECT. This means they return to the hospital every one–two months, as needed, for an additional treatment. These individuals are able to keep their illness under control and lead a normal and productive life.

Electrocution *see* **Electric shock injuries**

Electroencephalography

Definition

Electroencephalography, or EEG, is a neurological test that uses an electronic monitoring device to measure and record electrical activity in the brain.

Purpose

The EEG is a key tool in the diagnosis and management of **epilepsy** and other seizure disorders. It is also used to assist in the diagnosis of brain damage and disease (e.g., **stroke**, tumors, encephalitis), intellectual disabilities (ID), **sleep disorders**, degenerative diseases such as Alzheimer's disease and Parkinson's disease, and certain mental disorders (e.g., **alcoholism**, **schizophrenia**, **autism**).

An EEG may also be used to monitor brain activity during surgery and to determine brain death.

Precautions

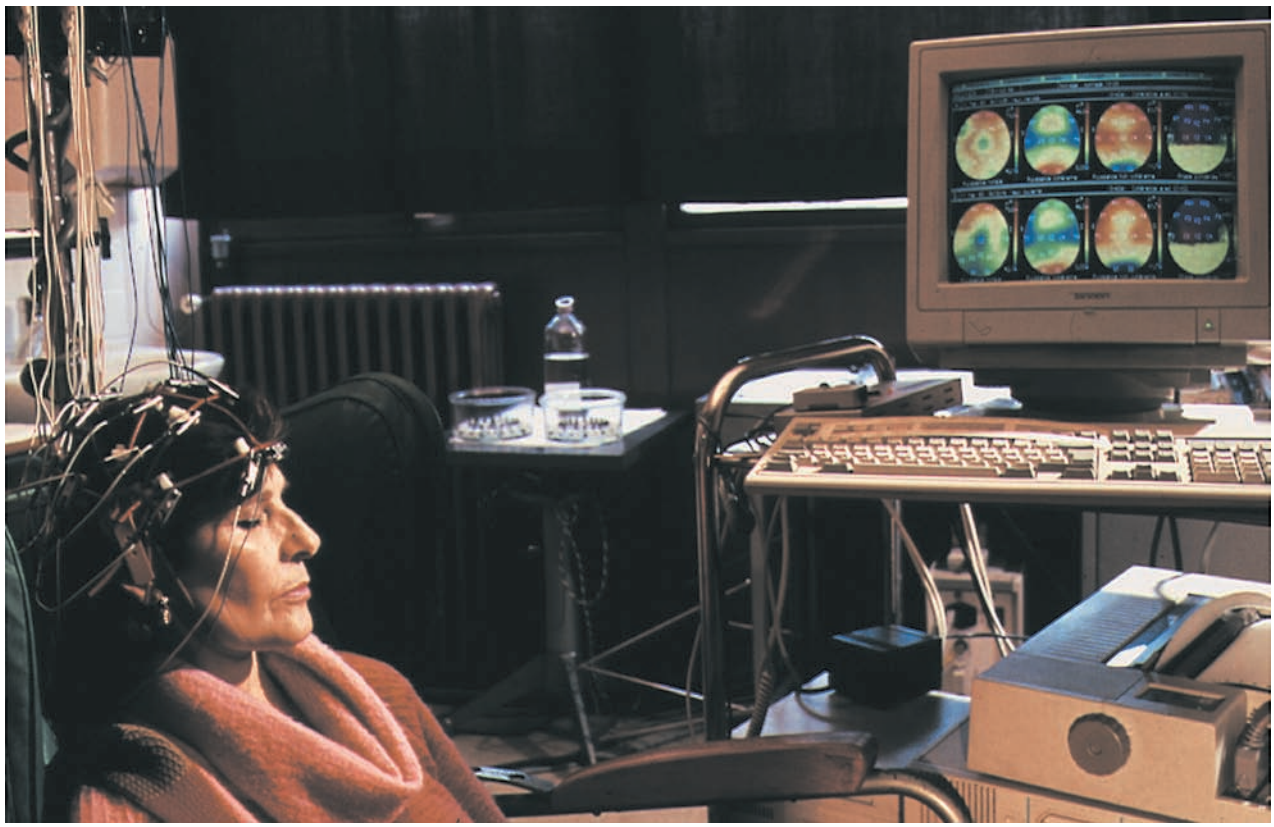
Electroencephalography should be administered and interpreted by a trained medical professional only. Data from an EEG is only one element of a complete medical and/or psychological patient assessment, and should never be used alone as the sole basis for a diagnosis.

Description

Before the EEG begins, a nurse or technician attaches approximately 16–20 electrodes to the patient's scalp with a conductive, washable paste. Depending on the purpose for the EEG, implantable or invasive electrodes are occasionally used. Implantable electrodes include sphenoidal electrodes, which are fine wires inserted under the zygomatic arch, or cheekbone; and depth electrodes, which are surgically-implanted into the brain. The EEG electrodes are painless, and are used to measure the electrical activity in various regions of the brain.

For the test, the patient lies on a bed, padded table, or comfortable chair and is asked to relax and remain still during the EEG testing period. An EEG usually takes no more than one hour. During the test procedure, the patient may be asked to breathe slowly or quickly; visual stimuli such as flashing lights or a patterned board may be used to stimulate certain types of brain activity. Throughout the procedure, the electroencephalograph machine makes a continuous graphic record of the patient's brain activity, or brainwaves, on a long strip of recording paper or

WWW.BOOKBAZ.IR



This woman is undergoing an electroencephalogram (EEG) to diagnose Alzheimer's disease. On the computer screen at the right are the colored scans of the electrical activity in her brain. Alzheimer's patients show a specific abnormality in their EEGs. *(Catherine Pouedras/Photo Researchers, Inc.)*

on a computer screen. This graphic record is called an electroencephalogram.

The sleep EEG uses the same equipment and procedures as a regular EEG. Patients undergoing a sleep EEG are encouraged to fall asleep completely rather than just relax. They are typically provided a bed and a quiet room conducive to sleep. A sleep EEG lasts up to three hours.

In an ambulatory EEG, patients are hooked up to a portable cassette recorder. They then go about their normal activities, and take their normal rest and sleep for a period of up to 24 hours. During this period, the patient and patient's family record any symptoms or abnormal behaviors, which can later be correlated with the EEG to see if they represent seizures.

Many insurance plans provide reimbursement for EEG testing. Costs for an EEG range from $100 to more than $500, depending on the purpose and type of test (i.e., asleep or awake, and invasive or non-invasive electrodes). Because coverage may be dependent on the disorder or illness the EEG is evaluating, patients should check with their individual insurance plan.

Preparation

Full instructions should be given to EEG patients when they schedule their test. Typically, individuals on medications that affect the central nervous system, such as anticonvulsants, stimulants, or antidepressants, are told to discontinue their prescription for a short time prior to the test (usually one to two days). Patients may be asked to avoid food and beverages that contain **caffeine**, a central nervous system stimulant. However, any such request should be cleared by the treating physician. Patients may also be asked to arrive for the test with clean hair free of spray or other styling products.

Patients undergoing a sleep EEG may be asked to remain awake the night before their test. They may be given a sedative prior to the test to induce sleep.

KEY TERMS

Epilepsy—A neurological disorder characterized by recurrent seizures with or without a loss of consciousness.

Ictal EEG—Used to measure brain activity during a seizure. May be useful in learning more about patients who are not responding to conventional treatments.

Aftercare

If the patient has suspended regular medication for the test, the EEG nurse or technician should advise him when he can begin taking it again.

Risks

Being off medication for 1–2 days may trigger seizures. Certain procedures used during EEG may trigger seizures in patients with epilepsy. Those procedures include flashing lights and deep breathing. If the EEG is being used as a diagnostic for epilepsy (i.e., to determine the type of seizures an individual has), this may be a desired effect, although the patient needs to be monitored closely so that the seizure can be aborted if necessary. This type of test is known as an ictal EEG.

Results

In reading and interpreting brainwave patterns, a neurologist or other physician will evaluate the type of brainwaves and the symmetry, location, and consistency of brainwave patterns. He will also look at the brainwave response to certain stimuli presented during the EEG test (such as flashing lights or noise). There are four basic types of brainwaves: alpha, beta, theta, and delta. "Normal" brainwave patterns vary widely, depending on factors of age and activity. For example, awake and relaxed individuals typically register an alpha wave pattern of 8–13 cycles per second. Young children and sleeping adults may have a delta wave pattern of under four cycles per second.

The EEG readings of patients with epilepsy or other seizure disorders display bursts or spikes of electrical activity. In focal epilepsy, spikes are restricted to one hemisphere of the brain. If spikes are generalized to both hemispheres of the brain, multifocal epilepsy may be present.

The diagnostic brainwave patterns of other disorders varies widely. The appearance of excess theta waves (4–8 cycles per second) may indicate brain injury. Brain wave patterns in patients with brain disease, ID, and brain injury show overall slowing. A trained medical specialist should interpret EEG results in the context of the patient's medical history, and other pertinent medical test results.

Electrolyte disorders

Definition

An electrolyte disorder is an imbalance of certain ionized components (i.e., bicarbonate, **calcium**, chloride, magnesium, phosphate, potassium, and **sodium**) in the blood.

Description

Electrolytes are ionized molecules found throughout the blood, tissues, and cells of the body. These molecules, which are either positive (cations) or negative (anions), conduct an electric current and help to balance pH and acid-base levels in the body. Electrolytes also facilitate the passage of fluid between and within cells through a process known as osmosis and play a part in regulating the function of the cardiovascular, neuromuscular, endocrine, and excretory systems.

The serum electrolytes include:

- Sodium (Na). A positively charged electrolyte that helps to balance fluid levels in the body and facilitates neuromuscular functioning.
- Potassium (K). A main component of cellular fluid, this positive electrolyte helps to regulate neuromuscular function and osmotic pressure.
- Calcium (Ca). A cation, or positive electrolyte, that affects neuromuscular performance and contributes to skeletal growth and blood coagulation.
- Magnesium (Mg). Influences muscle contractions and intracellular activity. A cation.
- Chloride (Cl). An anion, or negative electrolyte, that regulates blood pressure.
- Phosphate (HPO_4). Negative electrolyte that impacts metabolism and regulates acid-base balance and calcium levels.

WWW.BOOKBAZ.IR

- Bicarbonate (HCO_3). A negatively charged electrolyte that assists in the regulation of blood pH levels. Bicarbonate insufficiencies and elevations cause acid-base disorders (i.e., acidosis, alkalosis).

Risk factors

Medications, chronic diseases, and **trauma** (for example, **burns**, or **fractures**, etc.) may cause the concentration of certain electrolytes in the body to become too high (hyper-) or too low (hypo-). When this happens, an electrolyte imbalance, or disorder, results.

Causes and symptoms

Sodium

HYPERNATREMIA. Sodium helps the kidneys to regulate the amount of water the body retains or excretes. Consequently, individuals with elevated serum sodium levels experience a loss of fluids, or **dehydration**. **Hypernatremia** can be caused by inadequate water intake, excessive fluid loss (i.e., **diabetes insipidus**, **kidney disease**, severe burns, and prolonged **vomiting** or **diarrhea**), or sodium retention (caused by excessive sodium intake or aldosteronism). In addition, certain drugs, including loop **diuretics**, **corticosteroids**, and antihypertensive medications may cause elevated sodium levels.

Symptoms of hypernatremia include:

- thirst
- orthostatic hypotension
- dry mouth and mucous membranes
- dark, concentrated urine
- loss of elasticity in the skin
- irregular heartbeat (tachycardia)
- irritability
- fatigue
- lethargy
- heavy, labored breathing
- muscle twitching and/or seizures

HYPONATREMIA. Up to 1% of all hospitalized patients and as many as 18% of nursing home patients develop **hyponatremia**, making it one of the most common electrolyte disorders. Diuretics, certain psychoactive drugs (i.e., fluoxetine, sertraline, haloperidol), specific antipsychotics (lithium), vasopressin, chlorpropamide, the illicit drug ecstasy, and other pharmaceuticals can cause decreased sodium levels. Low sodium levels may also be triggered by inadequate dietary intake of sodium, excessive perspiration, water intoxication, and impairment of adrenal gland or kidney function.

Symptoms of hyponatremia include:

- nausea, abdominal cramping, and/or vomiting
- headache
- edema (swelling)
- muscle weakness and/or tremor
- paralysis
- disorientation
- slowed breathing
- seizures
- coma

Potassium

HYPERKALEMIA. **Hyperkalemia** may be caused by ketoacidosis (diabetic **coma**), myocardial infarction (**heart attack**), severe burns, kidney failure, **fasting**, **bulimia nervosa**, gastrointestinal bleeding, adrenal insufficiency, or Addison's disease. Diuretic drugs, cyclosporin, lithium, heparin, ACE inhibitors, **beta blockers**, and trimethoprim can increase serum potassium levels, as can heavy **exercise**. The condition may also be secondary to hypernatremia. Symptoms may include:

- weakness
- nausea and/or abdominal pain
- irregular heartbeat (arrhythmia)
- diarrhea
- muscle pain

HYPOKALEMIA. Severe dehydration, aldosteronism, Cushing's syndrome, kidney disease, long-term diuretic therapy, certain **penicillins**, laxative abuse, **congestive heart failure**, and adrenal gland impairments can all cause depletion of potassium levels in the bloodstream. A substance known as glycyrrhetinic acid, which is found in licorice and chewing tobacco, can also deplete potassium serum levels. Symptoms of **hypokalemia** include:

- weakness
- paralysis
- increased urination
- irregular heartbeat (arrhythmia)
- orthostatic hypotension
- muscle pain
- tetany

Calcium

HYPERCALCEMIA. Blood calcium levels may be elevated in cases of thyroid disorder, **multiple myeloma**, metastatic cancer, multiple bone fractures, milk-alkali syndrome, and Paget's disease. Excessive use of calcium-containing supplements and certain over-the-counter medications (i.e., **antacids**) may also cause **hypercalcemia**. In infants, lesser known causes may include blue diaper syndrome, Williams syndrome, secondary **hyperparathyroidism** from maternal **hypocalcemia**, and dietary phosphate deficiency. Symptoms include:

- fatigue
- constipation
- depression
- confusion
- muscle pain
- nausea and vomiting
- dehydration
- increased urination
- irregular heartbeat (arrhythmia)

HYPOCALCEMIA. Thyroid disorders, kidney failure, severe burns, **sepsis**, **vitamin D** deficiency, and medications such as heparin and glucogan can deplete blood calcium levels. Lowered levels cause:

- muscle cramps and spasms
- tetany and/or convulsions
- mood changes (depression, irritability)
- dry skin
- brittle nails
- facial twitching

Magnesium

HYPERMAGNESEMIA. Excessive magnesium levels may occur with end-stage renal disease, Addison's disease, or an overdose of magnesium salts. Hypermagnesemia is characterized by:

- lethargy
- hypotension
- decreased heart and respiratory rate
- muscle weakness
- diminished tendon reflexes

HYPOMAGNESEMIA. Inadequate dietary intake of magnesium, often caused by chronic **alcoholism** or **malnutrition**, is a common cause of hypomagnesemia. Other causes include malabsorption syndromes, **pancreatitis**, aldosteronism, burns, hyperparathyroidism, digestive system disorders, and diuretic use. Symptoms of low serum magnesium levels include:

- leg and foot cramps
- weight loss
- vomiting
- muscle spasms, twitching, and tremors
- seizures
- muscle weakness
- arrthymia

Chloride

HYPERCHLOREMIA. Severe dehydration, kidney failure, hemodialysis, **traumatic brain injury**, and aldosteronism can cause hyperchloremia. Drugs such as boric acid and ammonium chloride and the intravenous (IV) infusion of sodium chloride can also boost chloride levels, resulting in hyperchloremic **metabolic acidosis**. Symptoms include:

- weakness
- headache
- nausea
- cardiac arrest

HYPOCHLOREMIA. Hypochloremia usually occurs as a result of sodium and potassium depletion (i.e., hyponatremia, hypokalemia). Severe depletion of serum chloride levels causes **metabolic alkalosis**. This alkalization of the bloodstream is characterized by:

- mental confusion
- slowed breathing
- paralysis
- muscle tension or spasm

Phosphate

HYPERPHOSPHATEMIA. Skeletal fractures or disease, kidney failure, **hypoparathyroidism**, hemodialysis, **diabetic ketoacidosis**, **acromegaly**, systemic infection, and intestinal obstruction can all cause phosphate retention and build-up in the blood. The disorder occurs concurrently with hypocalcemia. Individuals with mild hyperphosphatemia are typically asymptomatic, but signs of severe hyperphosphatemia include:

- tingling in hands and fingers
- muscle spasms and cramps
- convulsions
- cardiac arrest

HYPOPHOSPHATEMIA. Serum phosphate levels of 2 mg/dL or below may be caused by hypomagnesemia and hypokalemia. Severe burns, alcoholism, diabetic

WWW.BOOKBAZ.IR

KEY TERMS

Acid-base balance—A balance of acidity and alkalinity of fluids in the body that keeps the pH level of blood around 7.35–7.45.

Addison's disease—A disease characterized by a deficiency in adrenocortical hormones due to destruction of the adrenal gland.

Aldosteronism—A condition defined by high serum levels of aldosterone, a hormone secreted by the adrenal gland that is responsible for increasing sodium reabsorption in the kidneys.

Bulimia nervosa—An eating disorder characterized by binging and purging (self-induced vomiting) behaviors.

Milk-alkali syndrome—Elevated blood calcium levels and alkalosis caused by excessive intake of milk and alkalis. Usually occurs in the treatment of peptic ulcer.

Orthostatic hypotension—A drop in blood pressure that causes faintness or dizziness and occurs when one rises to a standing position. Also known as postural hypotension.

Osmotic pressure—Pressure that occurs when two solutions of differing concentrations are separated by a semipermeable membrane, such as a cellular wall, and the lower concentration solute is drawn across the membrane into the higher concentration solute (osmosis).

Tetany—A disorder of the nervous system characterized by muscle cramps, spasms of the arms and legs, and numbness of the extremities.

ketoacidosis, kidney disease, hyperparathyroidism, **hypothyroidism**, Cushing's syndrome, malnutrition, hemodialysis, vitamin D deficiency, and prolonged diuretic therapy can also diminish blood phosphate levels. There are typically few physical signs of mild phosphate depletion. Symptoms of severe hypophosphatemia include:

- muscle weakness
- weight loss
- bone deformities (osteomalacia)

Diagnosis

Examination

Diagnosis is performed by a physician or other qualified healthcare provider who will take a medical history, discuss symptoms, perform a complete **physical examination**, and prescribe appropriate laboratory tests. Because electrolyte disorders commonly affect the neuromuscular system, the provider will test reflexes. If a calcium imbalance is suspected, the physician will also check for Chvostek's sign, a reflex test that triggers an involuntary facial twitch, and Trousseau's sign, a muscle spasm that occurs in response to pressure on the upper arm.

Tests

Serum electrolyte imbalances can be detected through blood tests. Blood is drawn from a vein on the back of the hand or inside of the elbow by a medical technician, or phlebotomist, and analyzed at a lab.

Normal levels of electrolytes are:

- Sodium: 135–145 mEq/L (serum)
- Potassium: 3.5–5.5 mEq/L (serum)
- Calcium: 8.8–10.4 mg/dL (total Ca; serum); 4.7–5.2 mg/dL (unbound Ca; serum)
- Magnesium: 1.4–2.1 mEq/L (plasma)
- Chloride: 100–108 mEq/L (serum)
- Phosphate: 2.5–4.5 mg/dL (plasma; adults)

Standard ranges for test results may vary due to differing laboratory standards and physiological variances (gender, age, and other factors). Other blood tests that determine pH levels and acid-base balance may be performed.

Treatment

Treatment of electrolyte disorders depends on the underlying cause of the problem and the type of electrolyte involved. If the disorder is caused by poor diet or improper fluid intake, nutritional changes may be prescribed. If medications such as diuretics triggered the imbalance, discontinuing or adjusting the drug therapy may effectively treat the condition. Fluid and electrolyte replacement therapy, either intravenously or by mouth, can reverse electrolyte depletion.

Hemodialysis treatment may be required to reduce serum potassium levels in hyperkalemic patients with impaired kidney function. It may also be recommended for renal patients with severe hypermagnesemia.

Prognosis

A patient's long-term prognosis depends upon the root cause of the electrolyte disorder. When treated quickly and appropriately, electrolyte imbalances in and of themselves are usually effectively reversed.

When they are mild, some electrolyte imbalances have few to no symptoms and may pass unnoticed. For example, transient hyperphosphatemia is usually fairly benign. However, long-term elevations of blood phosphate levels can lead to potentially fatal soft tissue and vascular calcifications and bone disease, and severe serum phosphate deficiencies (hypophosphatemia) can cause **encephalopathy**, coma, and death.

Severe hypernatremia has a mortality rate of 40–60%. Death is commonly due to cerebrovascular damage and hemorrhage resulting from dehydration and shrinkage of the brain cells.

Prevention

Physicians should use caution when prescribing drugs known to affect electrolyte levels and acid-base balance. Individuals with kidney disease, thyroid problems, and other conditions that may place them at risk for developing an electrolyte disorder should be educated on the signs and symptoms.

Electrolyte supplements

Definition

Electrolyte supplements are a varied group of prescription and nonprescription preparations used to correct imbalances in the body's electrolyte levels. Electrolytes themselves are substances that dissociate into ions (electrically charged atoms or atom groups) when they melt or are dissolved, thus serving to conduct electricity. In the human body, electrolytes are critical to the proper distribution of water, muscle contraction and expansion, transmission of nerve impulses, delivery of oxygen to body tissues, heart rate and rhythm, acid-base balance, and other important functions or conditions.

The ions that are formed when electrolytes are dissolved in body fluids are either positively or negatively charged. Positively charged ions are called cations, and are formed when an atom or atom group loses electrons. The most important cations in the human body are **sodium**, potassium, magnesium, and **calcium** ions. Negatively charged ions are called anions, and are formed when an atom or atom group gains electrons. The principal anions in the body include bicarbonate, chloride, phosphate, and sulfate ions, as well as ions formed by certain protein compounds or organic acids.

About 60% of an adult human male's total body weight is water. In adult women, the figure is about 55%, and is even lower in the elderly and in obese people. Two-thirds of total body water (TBW) lies inside cells and is known as intracellular fluid or ICF. The remaining third of TBW lies outside the cells and is called extracellular fluid or ECF. About 75% of ECF lies in connective tissue or the spaces between tissues outside the blood vessels (interstitial spaces), while the remaining 25% is within the blood vessels. In addition to representing different proportions of TBW, ICF and ECF differ significantly in their electrolyte content. Whereas the major cation in ICF is potassium, the most important cation in ECF is sodium. These differences in electrolyte levels help to regulate the movement of water between ICF and ECF.

Children are more vulnerable than adults to fluid and electrolyte imbalances, in part because they have different ratios of TBW to total body weight, and of ICF to ECF. A newborn baby carried to full term has a TBW ratio between 75% and 80%. The baby's total body water ratio decreases by 4–5% during the first week after birth and reaches the adult level of 60% by 12 months of age. Similarly, a newborn has an ICF:ECF ratio of 55:45, which falls to the adult ratio of 70:30 during the first year of life. In addition to these different fluid ratios, children's kidneys are less efficient than adults in regulating water balance; children have smaller organ systems that dissipate body heat less efficiently; and their core body temperature rises faster than that of an adult when they become dehydrated. All these factors help to explain why some electrolyte supplements are formulated specifically for children.

Purpose

The purpose of electrolyte supplements is to restore the proper ratio of total body water to total

WWW.BOOKBAZ.IR

body weight and the correct proportions of the various electrolytes in body fluids. Electrolyte imbalances may result from excessive intake or inadequate elimination of electrolytes on the one hand or by insufficient intake or excessive elimination on the other hand.

Body regulation of water and electrolytes

Under normal conditions, the water and electrolyte content of the body is regulated by the kidneys, the secretion of antidiuretic hormone, and the sensation of thirst. The average adult needs to take in about 700–800 mL (about 1.5–1.7 pints) of water per day in order to match the water lost through perspiration, breathing, and excretion of waste products (urine and feces). The water taken in by mouth is added to the 200–300 mL (0.42–0.63 pints) of water that are formed in the body each day through tissue breakdown.

The amount of water needed to match fluid losses may be considerably greater than the average during **exercise** or in patients with **fever**, severe **vomiting**, or **diarrhea**. Adults with fever typically lose an additional 0.75–1.0 oz of fluid per day for each degree that their temperature rises above normal. With regard to diarrhea, adults with **cholera** have been reported to lose as much as a quart of fluid per hour in their stools. The fluid lost in this way contains sodium, potassium, and chloride, resulting in electrolyte imbalances in cholera patients as well as **dehydration**.

Exercise raises the total metabolism of the body to 5–15 times the resting rate. Most of this energy (70–90%) is released as heat, which is partially dissipated by the evaporation of sweat. Depending on weather conditions, the type and weight of clothing being worn, and the intensity of exercise or physical work performed, adults may lose anywhere from 1–2.5 qt of fluid per hour through perspiration. Sweat contains sodium chloride as well as smaller amounts of potassium, calcium, and magnesium. In order to maintain the proper balance of electrolytes in the body as well as fluid, athletes or people employed in outdoor work during warm weather may need to replace the electrolytes lost in sweat by taking capsules or drinking beverages containing supplemental electrolytes.

With regard to the sense of thirst, it is not always an accurate indication of the body's need for water. Researchers have found that many people do not feel thirsty until they have already lost about 2% of their total body weight through fluid losses. As a result, most people do not replace enough fluid during exercise or hot weather simply by drinking water until they no longer feel thirsty. In addition, the **aging** process, certain mental disorders, or drugs may affect a person's sense of thirst.

At the other extreme of water intake, a person may drink excessive amounts of water due to misunderstandings about their need for extra fluid during exercise. This condition is known as water intoxication or hyperhydration. It leads to abnormally low levels of sodium in the blood, a condition known as **hyponatremia**. This condition is also known as exercise-associated hyponatremia (EAH). Water intoxication may lead to swelling of the brain, confusion, disorientation, and eventually **coma** or death. Several marathon runners have died from water intoxication, as have teenagers who consumed large amounts of water after taking doses of Ecstasy (MDMA), a so-called "club drug." Other persons at risk for water intoxication include people with **eating disorders** and children with intellectual disabilities (ID). Research reported in the *New England Journal of Medicine* revealed that as many as 13% of marathon runners developed hyponatremia during the course of a race as a result of drinking too much water, usually 3 qt or more. Female athletes appear to be at greater risk of water intoxication and hyponatremia than male athletes.

Conditions associated with fluid and electrolyte imbalance

Several common conditions can lead to fluid and electrolyte imbalance:

- Exposure to extended periods of extremely hot weather.
- High levels of athletic activity, military training, or outdoor work in such fields as construction, agriculture, forestry, fishing, and certain types of manufacturing.
- Extreme changes in diet.
- Reduced fluid intake.
- Medication side effects. Certain drugs, particularly diuretics, beta-blockers, and vasodilators, may increase the loss of electrolytes in urine and/or interfere with the body's ability to regulate its temperature during exercise or in hot weather.
- Severe illnesses characterized by high fever, recurrent diarrhea, and/or frequent vomiting. Such illnesses include cholera, viral gastroenteritis (stomach flu), shigellosis, and amebic dysentery.
- Severe burns covering more than 10% of the body.
- Surgical creation of a stoma or urinary diversion. These operations sometimes lead to an increased loss of body fluids while the patient's body is adjusting to the changes in urination and excretion resulting from the surgery. In addition, some forms of

weight loss surgery intended to bypass parts of the small intestine in which food absorption occurs have a 70% rate of electrolyte imbalances as a complication of the operation.

- Diseases affecting the kidneys. These include diabetes mellitus, diabetes insipidus, and syndrome of inappropriate antidiuretic hormone secretion (SIADH) as well as cancer or infections of the kidneys.
- In infants, premature birth.

Description

The various electrolyte supplements used in the United States and Canada are intended to prevent or treat electrolyte imbalances in very different situations or groups of patients. They range from sports drinks and other supplements used by amateur or professional athletes to prevent **muscle cramps** and improve athletic performance, to liquids used at home to prevent dehydration in children with diarrhea, to injections administered as part of enteral (feeding through a tube or stoma directly into the small intestine) or **parenteral nutrition** (intravenous feeding that bypasses the digestive tract).

The major categories of electrolyte supplements are:

- Sports drinks. Sports drinks are beverages specially formulated to contain appropriate amounts of electrolytes and carbohydrates as well as water to replace the fluid and sodium lost through sweat during athletic activities. These beverages are popular with athletes at the college level. According to the American College of Sports Medicine as well as American and Canadian dietitians' associations, sports drinks are effective in supplying food energy for the muscles, maintaining proper levels of blood sugar, maintaining the proper functioning of the thirst mechanism, and lowering the risk of dehydration or hyponatremia. Other researchers have noted that the flavoring added to sports drinks encourages athletes to drink more during periods of exercise and thus maintain proper levels of hydration. Sports drinks can be purchased in supermarkets and health food stores; they include such well-known beverages as Gatorade and Powerade. Some of these supplements come in a semisolid form known as energy gels, which contain caffeine or various herbal compounds as well as carbohydrates and electrolytes.
- Over-the-counter powders and tablets. Some athletes–particularly those who participate in long-distance running or endurance cycling—prefer capsules or concentrated powders to maintain their electrolyte balance during exercise. The powders are mixed with 12–16 oz of cold water prior to drinking, while the capsules can be taken before, during, and after exercise. Most contain flavorings to mask the naturally salty or bitter taste of the electrolytes themselves. Common brand names include eForce, Nutri-Biotic, and Endurolytes;. These products are regarded by the Food and Drug Administration (FDA) as dietary supplements.
- Over-the-counter electrolyte replenishers for children. Infants and young children are more vulnerable to dehydration than adults, particularly from severe gastroenteritis or diarrhea. A child may become dehydrated in less than a day from recurrent vomiting or episodes of diarrhea. Some doctors recommend that parents keep oral rehydration fluids containing mixtures of carbohydrates and electrolytes specially formulated for children in the medicine chest at home in case the child becomes dehydrated from a stomach virus or similar illness. Common brand names for these products, which are regulated by the FDA as medical foods, include Pedialyte, Infalyte, Naturalyte, and Rehydralyte. Most come in a powdered form to be mixed with water as well as liquid forms; Pedialyte is also available as fruit-flavored freezer pops.
- Oral rehydration formulae for children and adults. Oral rehydration salts, also known as ORS, have been a staple of treatment for cholera and other diseases accompanied by severe diarrhea in developing countries for almost half a century. First researched in the 1940s, oral rehydration salts were adopted by the World Health Organization (WHO) in 1978 in order to reduce the risk of death from dehydration caused by cholera-related diarrhea. Since the introduction of ORS, the number of children around the world who die from acute diarrhea has been reduced from 5 million per year to 1.3 million. Reformulated by WHO in 2002, the ORS salts come in packets to be kept in the home and mixed with water as soon as a child (or adult) falls ill. The formula is a low-glucose and low-sodium mixture. If the WHO packets are unavailable, a comparable form of oral rehydration solution can be made by adding 8 tsp of table sugar, ½ tsp of salt, ½ tsp of baking soda (bicarbonate of soda), and $^1/_3$ tsp of potassium chloride to 1 L (1.05 qt) of water. In an emergency, a solution prepared from 1 tbsp of sugar and ½ tsp of salt added to 1 L of water can be used to treat diarrhea.
- Multiple electrolyte injections. Various mixtures of electrolytes are available by prescription in injectable form to be added to enteral or parenteral nutrition formulae. These forms of feeding are used in patients

WWW.BOOKBAZ.IR

KEY TERMS

Anion—An ion carrying a negative charge owing to a surplus of electrons. Anions in the body include bicarbonate, chloride, phosphate, sulfate, certain organic acids, and certain protein compounds.

Cation—An ion carrying a positive charge due to a loss of electrons. Cations in the body include sodium, potassium, magnesium, and calcium ions.

Cholera—A severe bacterial infection of the small intestine characterized by profuse diarrhea and eventual dehydration. Cholera is still a frequent cause of death among children in developing countries.

Electron—An elementary particle carrying a negative charge. Electrons may exist either independently or as components of an atom outside its nucleus.

Enteral nutrition—Nourishment given through a tube or stoma directly into the small intestine, thus bypassing the upper digestive tract.

Hyponatremia—Insufficient sodium in the blood.

Interstitial spaces—Spaces within body tissues that are outside the blood vessels. Also known as interstitial compartments.

Ion—An atom or group of atoms that acquires an electrical charge by the gain or loss of electrons.

Metabolism—The sum of an organism's physical and chemical processes that produce and maintain living tissue, and make energy available to the organism. Insulin resistance is a disorder of metabolism.

Parenteral nutrition—Nutrition supplied intravenously, thus bypassing the patient's digestive tract entirely.

Stoma—A surgical opening made in the abdominal wall to allow waste products to pass directly to the outside.

Water intoxication—A potentially life-threatening condition caused by drinking too much water, which leads to hyponatremia and may result in seizures, coma, and death.

who require supplementation or complete replacement of feeding by mouth, including patients with various intestinal disorders, AIDS, or severe burns. Basic solutions for total parenteral nutrition, or TPN, contain the electrolytes sodium, potassium, chloride, phosphate, and magnesium, although the exact proportion of electrolytes can be tailored to an individual patient's needs. Some injectable formulae contain dextrose, a sugar, and acetate or lactate as well as the five major electrolytes. Common brand names include TPN Electrolytes, Lypholyte, Nutrilyte, Plasma-Lyte 148, and others. Some patients are taught to use these injectable formulae at home.

Recommended dosage

Recommended dosages for electrolyte supplements are:

- Sports drinks. Since sports drinks and energy gels are not medications in the strict sense, the amount consumed will vary not only from person to person but also in a given individual from day to day depending on weather conditions, level of athletic conditioning, length of activity, and other factors. To lower the risk of dehydration in adults in hot weather, the American College of Sports Medicine recommends drinking approximately 2–3 mL/lb of body weight of water or sports drink four hours before exercising. Overhydration during this time period should be avoided. During exercise, enough fluid should be consumed to prevent a water deficit greater then 2% of body weight. Recommended beverages are those that contain electrolytes and carbohydrates. If the exercise event lasts longer than an hour, consumption of carbohydrate beverages that contain 6–8% carbohydrate is recommended. After exercise, rapid and complete recovery from exercise-induced dehydration can be accomplished by drinking at least 16–24 oz (450–675 mL) of fluid for every pound of weight lost during exercise. To replace fluids and electrolytes lost during endurance events lasting longer than two hours, the current recommendation is consumption of sports drinks that contain 0.5–0.7 g/L of sodium and 0.8–2.0 g/L of potassium and that also contain carbohydrate.
- Over-the-counter powders and tablets. The usual recommended dose of powdered electrolytes is one scoopful (or prepackaged envelope) of powder dissolved in 12–16 oz of water before exercising. Capsules may be taken as follows: 1–3 capsules 30–60 minutes before exercising; 1–6 capsules per hour during the workout; and 1–3 capsules after exercising.
- Over-the-counter electrolyte replenishers for children. Dosages for Pedialyte and similar oral rehydration

solutions for children are usually based on the child's age and weight. The child's doctor should determine the quantity to be given if the child is younger than 12 months of age. Children between the ages of one and two years are usually given 34 mL of electrolyte solution per pound of body weight during the first eight hours of treatment and 75 mL per pound of body weight during the next 16 hours, although the doctor may adjust the dose if the child is very thirsty. Children between the ages of two and ten are given 23 mL of electrolyte solution per pound of body weight for the first four to six hours of treatment, followed by 45 mL per pound taken over the next 18–24 hours. Freezer pops may be given to children older than one year as often as the child desires.

- Oral rehydration formulae. The WHO form of oral rehydration liquid is made by adding the full contents of one packet of powdered oral rehydration salts to a quart of drinking water. The solution should not be boiled. A fresh quart of solution should be mixed each day. Infants and young children should be given the solution in small amounts by spoon as often as possible. Adults and teenagers should take the WHO formula according to the doctor's directions.
- Multiple electrolyte injections. Basic TPN solutions are usually made up in liter batches and adjusted to each individual patient's needs. The standard adult dosage is 2 L per day, usually administered by drip through a needle or catheter placed in the patient's vein for a 10–12-hour period once a day or five days per week. The patient may be given several units of premixed TPN fluid to store at home in the refrigerator or freezer. Each dose should be taken from the refrigerator 4–6 hours prior to use to allow it to warm to room temperature. TPN solution stored in a freezer should be moved to a refrigerator 24 hours before use.

Precautions

Sports drinks should not be given to rehydrate children with vomiting or diarrhea, as they do not contain the proper balance of carbohydrates and electrolytes needed by children's bodies.

Over-the-counter powders and tablets should always be taken with adequate amounts of water and kept out of the reach of children.

Over-the-counter electrolyte replenishers for children should be stored out of the reach of children and away from heat and direct sunlight. In addition, they should not be given to patients with intestinal blockage.

WHO oral rehydration salts and packets of similar formulae should not be stored in damp places, as moisture can cause the contents to lose their effectiveness. These products should also be kept away from heat or direct sunlight. Unused oral rehydration solution should be discarded at the end of each day. As with electrolyte replenishers for children, oral rehydration formulae should not be given to patients with intestinal blockage.

Patients using multiple electrolyte injections as part of total parenteral **nutrition** should have their blood and urine checked at regular intervals while they are receiving these medicines. They should also be taught to recognize the signs of infection at the injection site (**pain**, swelling, redness, or a cold sensation). In addition, these patients should not use sports drinks, other electrolyte supplements, or over-the-counter medications (including herbal preparations) without consulting their doctor. The injections should not be used if the fluid looks cloudy, has solid particles floating in it, or has separated. The injections should be stored away from sunlight and moisture. In addition, patients receiving multiple electrolyte injections should not stop them suddenly without telling their doctor, as the dosage may need to be reduced slowly before the TPN is discontinued.

Side effects

Some persons do not like the salty taste of many sports drinks. They may wish to consider products containing glycine, which is an amino acid that neutralizes the salty taste of the electrolytes themselves. A more serious side effect of sports drinks is **tooth decay**. An article published by researchers at the University of Maryland Dental School showed that sports drinks erode tooth enamel at a rate three to 11 times faster than cola-based soft drinks.

No side effects have been reported for over-the-counter powders and tablets.

Side effects from children's electrolyte replenishers may include allergic reactions, including **hives**, swelling of the face or hands, trouble breathing, tingling in the mouth or throat. Other side effects may include signs of too much sodium in the body, such as **dizziness**, seizures, muscle twitching, or restlessness. The doctor should be notified immediately if any of these side effects occur. A less serious side effect that occurs in some children is mild vomiting.

Oral rehydration formulae may produce the same side effects as electrolyte replenishers for children.

Minor side effects from multiple electrolyte injections may include increased frequency of urination,

WWW.BOOKBAZ.IR

dry mouth, increased thirst, or drowsiness. Serious side effects include rapid weight gain, yellowing of the skin or eyes, fruity odor on the breath, numbness or tingling in the hands or feet, uneven heartbeat, **shortness of breath**, confusion, or weakness with muscle twitching. Patients should notify their doctor immediately if they notice any of these side effects.

Interactions

Sports drinks may raise blood electrolyte levels in patients receiving total parenteral nutrition. They should not be consumed by patients receiving multiple electrolyte injections.

Children receiving premixed forms of electrolyte replenishers should not eat food with added salt or drink fruit juices until the diarrhea has stopped.

No interactions with other medications have been reported with oral rehydration formulae for adults or over-the-counter powders and tablets. However, the doctor should be informed of all other medications the patient is taking in case a dosage adjustment is necessary.

Electrolyte tests

Definition

Electrolytes are positively and negatively charged molecules, called ions, that are found within cells, between cells, in the bloodstream, and in other fluids throughout the body. Electrolytes with a positive charge include **sodium**, potassium, **calcium**, and magnesium; the negative ions are chloride, bicarbonate, and phosphate. The concentrations of these ions in the bloodstream remain fairly constant throughout the day in a healthy person. Changes in the concentration of one or more of these ions can occur during various acute and chronic disease states and can lead to serious consequences.

Purpose

Tests that measure the concentration of electrolytes are useful in the emergency room and to obtain clues for the diagnosis of specific diseases. Electrolyte tests are used for diagnosing dietary deficiencies, excess loss of nutrients due to urination, **vomiting**, and **diarrhea**, or abnormal shifts in the location of an electrolyte within the body. When an abnormal electrolyte value is detected, the physician may either act to immediately correct the imbalance directly (in the case of an emergency) or run further tests to determine the underlying cause of the abnormal electrolyte value. Electrolyte disturbances can occur with malfunctioning of the kidney (renal failure), infections that produce severe and continual diarrhea or

vomiting, drugs that cause loss of electrolytes in the urine (**diuretics**), **poisoning** due to accidental consumption of electrolytes, or diseases involving hormones that regulate electrolyte concentrations.

Precautions

Electrolyte tests are performed from routine blood tests. The techniques are simple, automated, and fairly uniform throughout the United States. During the preparation of blood plasma or serum, health workers must take care not to break the red blood cells, especially when testing for serum potassium. Because the concentration of potassium within red blood cells is much higher than in the surrounding plasma or serum, broken cells would cause falsely elevated potassium levels.

Description

Electrolyte tests are typically conducted on blood plasma or serum, urine, and diarrheal fluids. Electrolytes can be classified in at least five different ways. One way is that some electrolytes tend to exist mostly inside cells, or are intracellular, while others tend to be outside cells, or are extracellular. Potassium, phosphate, and magnesium occur at much greater levels inside the cell than outside, while sodium and chloride occur at much greater levels extracellularly. A second classification distinguishes those electrolytes that participate directly in the transmission of nerve impulses and those that do not. Sodium, potassium, and calcium are the important electrolytes involved in nerve impulses, and disorders affecting them are most closely associated with neurological disorders. A third classification focuses on electrolytes that are able to form a tight union, or complex, with one another. Calcium and phosphate have the greatest tendency to form complexes with each other. Disorders that cause an increase in either plasma calcium or phosphate can result in the deposit of calcium-phosphate crystals in the soft tissues of the body. A fourth classification concerns those electrolytes that influence the acidity or alkalinity of the bloodstream, also known as the pH. The pH of the bloodstream is normally in the range of 7.35–7.45. A decrease below this range is called acidosis, while a pH above this range is called alkalosis. The electrolytes most closely associated with the pH of the bloodstream are bicarbonate, chloride, and phosphate.

Preparation

All electrolyte tests can be performed on plasma or serum. Plasma is prepared by withdrawing a blood sample and placing it in a test tube containing a chemical that prevents blood from clotting (an anticoagulant). Serum is prepared by withdrawing a blood sample, placing it in a test tube, and allowing it to clot. The blood spontaneously clots within a minute of withdrawing the blood from a vein. The serum or plasma is then rapidly spun with a centrifuge in order to remove the blood cells or clot.

Results

Electrolyte concentrations are similar whether measured in serum or plasma. Values can be expressed in terms of weight per unit volume (mg/deciliter; mg/dL) or in the number of molecules in a volume, or molarity (moles or millimoles/liter; M or mM). The range of normal values sometimes varies slightly between different age groups, for males and females, and between different analytical laboratories.

The normal level of serum sodium is in the range of 136–145 mM. The normal levels of serum potassium are 3.5–5.0 mM. Note that sodium occurs at a much higher concentration than potassium. The normal concentration of total serum calcium (bound calcium plus free calcium) is in the range of 8.8–10.4 mg/dL. About 40% of the total calcium in the plasma is loosely bound to proteins; this calcium is referred to as bound calcium. The normal range of free calcium is 4.8–5.2 mg/dL. The normal concentration of serum magnesium is in the range of 2.0–3.0 mg/dL.

The normal concentration range of chloride is 350–375 mg/dL or 98–106 mM. The normal level of phosphate, as expressed as the concentration of phosphorus, is 2.0–4.3 mg/dL. Bicarbonate is an electrolyte that is freely and spontaneously interconvertable with carbonic acid and carbon dioxide. The normal concentration of carbonic acid (H_2CO_3) is about 1.35 mM. The normal concentration of bicarbonate (HCO_3^-) is about 27 mM. The concentration of total carbon dioxide is the sum of carbonic acid and bicarbonate; this sum is normally in the range of 26–28 mM. The ratio of bicarbonate/carbonic acid is more significant than the actual concentrations of these two forms of carbon dioxide. Its normal value is 27/1.35 (equivalent to 20/1).

Positively charged electrolytes

High serum sodium levels (**hypernatremia**) occur at sodium concentrations over 145 mM, with severe hypernatremia over 152 mM. Hypernatremia is usually caused by diseases that cause excessive urination. In these cases, water is lost, but sodium is still retained

WWW.BOOKBAZ.IR

in the body. The symptoms include confusion and can lead to convulsions and **coma**. Low serum sodium levels (**hyponatremia**) are below 130 mM, with severe hyponatremia at or below 125 mM. Hyponatremia often occurs with severe diarrhea, with losses of both water and sodium, but with sodium loss exceeding water loss. Hyponatremia provokes clinical problems only if serum sodium falls below 125 mM, especially if this has occurred rapidly. The symptoms can be as mild as tiredness but may lead to convulsions and coma.

High serum potassium (**hyperkalemia**) occurs at potassium levels above 5.0 mM; it is considered severe over 8.0 mM. Hyperkalemia is relatively uncommon, but sometimes occurs in patients with kidney failure who take potassium supplements. Hyperkalemia can result in abnormal beating of the heart (cardiac **arrhythmias**). Low serum potassium (**hypokalemia**) occurs when serum potassium falls below 3.0 mM. It can result from low dietary potassium, as during **starvation** or in patients with **anorexia nervosa**; from excessive losses via the kidneys, as caused by diuretic drugs; or by diseases of the adrenal or pituitary glands. Mild hypokalemia causes muscle weakness, while severe hypokalemia can cause **paralysis**, the inability to breathe, and cardiac arrhythmias.

High levels of calcium ions (**hypercalcemia**) occur at free calcium ion concentrations over 5.2 mg/dL or total serum calcium above 10.4 mg/dL. Hypercalcemia usually occurs when the body dissolves bone at an abnormally fast rate, increasing both serum calcium and serum phosphate. Sudden hypercalcemia can cause vomiting and coma, while prolonged and moderate hypercalcemia results in the deposit of calcium phosphate crystals in the kidneys and eye. **Hypocalcemia** occurs when serum free calcium ions fall below 4.4 mg/dL, or when total serum calcium falls below 8.8 mg/dL. Hypocalcemia can result from **hypoparathyroidism** (low parathyroid hormone), from failure to produce 1,25-dihydroxyvitamin D, from low levels of plasma magnesium, and from phosphate poisoning (the phosphate enters the bloodstream and forms a complex with the free serum calcium). Hypocalcemia can cause depression and **muscle spasms**.

Hypermagnesemia occurs at serum magnesium levels over 25 mM (60 mg/dL). Hypermagnesemia is rare but can occur with the excessive consumption of magnesium salts. Hypomagnesemia occurs when serum magnesium levels fall below 0.8 mM, and can result from poor **nutrition**. Chronic **alcoholism** is the most common cause of hypomagnesemia, in part because of poor diet. Magnesium levels below 0.5 mM (1.2 mg/dL) cause serum calcium levels to decline. Some of the symptoms of hypomagnesemia, including twitching and convulsions, actually result from the concurrent hypocalcemia. Hypomagnesemia can also result in hypokalemia and thereby cause cardiac arrhythmias.

Negatively charged electrolytes

Serum chloride levels sometimes increase to abnormal levels as an undesirable side effect of medical treatment with sodium chloride or ammonium chloride. The toxicity of chloride results not from the chloride itself, but from the fact that the chloride occurs as the acid, hydrogen chloride (more commonly known as hydrochloric acid, or HCl). An overdose of chloride may cause the accumulation of hydrochloric acid in the bloodstream, with consequent acidosis. **Renal tubular acidosis**, one of many kidney diseases, involves the failure to release acid into the urine. The acidosis produces weakness, **headache**, nausea, and cardiac arrest. Low plasma chloride leads to the opposite situation: a decline in the acid content of the bloodstream. This is known as alkalization of the bloodstream, or alkalosis. Hydrochloric acid, originally from extracellular fluids, can be lost by vomiting. At its most severe, alkalosis results in paralysis (tetany).

Hyperphosphatemia occurs at serum phosphate levels above 5 mg/dL. It can result from the failure of the kidneys to excrete phosphate into the urine, causing phosphate to accumulate in the bloodstream. Hyperphosphatemia can also be caused by the impaired action of parathyroid hormone and by phosphate poisoning. Severe hyperphosphatemia can cause paralysis, convulsions, and cardiac arrest. These symptoms result because the phosphate, occurring in elevated levels, complexes with free serum calcium, resulting in hypocalcemia. Tests for heart function (an electrocardiogram) and parathyroid hormone levels are used in the diagnosis of hyperphosphatemia. Hypophosphatemia occurs if serum phosphorus falls to 2.0 mg/dL or lower. It often results from a shift of inorganic phosphate from the bloodstream to various organs and tissues. This shift can be caused by a rise in pH (alkalization) of the bloodstream, which can occur during hyperventilation, a reaction in various disease states. A shift in phosphate to intracellular tissues may draw calcium away from the bloodstream via the formation of insoluble calcium phosphate crystals within cells, with consequent hypocalcemia. Thus, tests for abnormalities in phosphate metabolism also involve tests for serum calcium.

Bicarbonate metabolism involves several compounds. When dietary starches, sugars, and fats are

broken down for energy production, carbon dioxide is created. Much of this carbon dioxide (CO_2) spontaneously converts to carbonic acid (H_2CO_3), and some of the carbonic acid spontaneously converts to bicarbonate (HCO_3^-) plus a hydrogen ion (H^-). Eventually, almost every molecule of carbon dioxide produced in the body, whether in the form of carbon dioxide, carbonic acid, or bicarbonate, must convert back to carbon dioxide in order to leave via the lungs during normal breathing.

If one holds one's breath, carbon dioxide cannot escape from the lungs, but continues to be generated within the body. This results in an increase in production of carbonic acid. A portion of the carbonic acid breaks apart (dissociates), causing an increase in hydrogen ions in the plasma, with a resulting acidosis. Tests for serum bicarbonate levels are accompanied by tests for acidosis (pH test). Conversely, when one breathes too rapidly (hyperventilation), the carbon dioxide is drawn off from the bloodstream and expelled in the breath at an increased rate. This results in an increase in the rate of combination of bicarbonate with hydrogen ions, resulting in alkalosis. Acidosis and alkalosis can be produced by means other than by altering the rate of breathing. The carbonic acid and bicarbonate in the bloodstream minimize (or buffer) any trend to acidosis or alkalosis. Tests for bicarbonate are generally accompanied by tests for blood pH and possibly tests for kidney malfunction, abnormal hormone function, or gastrointestinal disorders.

Electromyography

Definition

Electromyography (EMG) is a diagnostic procedure that is used to determine the health of muscles, along with the nerve cells that control these muscles, or what are called motor neurons. In purpose, the EMG is an electrical recording of muscle activity that aids in the diagnosis of neuromuscular disease. The EMG scan, sometimes also called a myogram, is used to identify the electrical signals that originate from these motor neurons (which cause the muscles to move). These electrical signals identified by the EMG allows the medical specialist to interpret such signals in order to diagnosis any problems within the muscles and the nerves that control them.

Description

During an EMG test, a fine needle is inserted into the muscle to be tested. This may cause some discomfort, similar to that of an injection. Recordings are made while the muscle is at rest, and then during the contraction. The person performing the test may move the limb being tested, and direct the patient to move it with various levels of force. The needle may be repositioned in the same muscle for further recording. Other muscles may be tested as well.

A slightly different test, the nerve conduction velocity test, is often performed at the same time with the same equipment. In this test, stimulating and recording electrodes are used, and small electrical shocks are applied to measure the ability of the nerve to conduct electrical signals. This test may cause mild tingling and discomfort similar to a mild **shock** from static electricity. Evoked potentials may also be performed for additional diagnostic information. Nerve conduction velocity and evoked potential testing are especially helpful when **pain** or sensory complaints are more prominent than weakness. The EMG procedure will take usually 30–60 minutes to complete.

Purpose

Muscles are stimulated by signals from nerve cells called motor neurons. This stimulation causes electrical activity in the muscle, which in turn causes contraction. An electrode, which consists of a very small, solid needle (pin), is inserted through the skin and into the muscle. It is connected to a recording device that detects this electrical activity. When a needle is used the process is called a needle EMG, or simply an EMG. The needle electrode and recorder pair is called an electromyography machine, which includes a monitor called an oscilloscope. A speaker is included, which provides crackling sounds as the electrical intensity rises and falls.

EMG can determine whether a particular muscle is responding appropriately to stimulation, and whether a muscle remains inactive when not stimulated. Thus, during the test, the patient will be asked to contract particular muscles, such as those in the leg. The electrical wave produced on the EMG machine will determine the condition of the muscle and nerves

WWW.BOOKBAZ.IR

as it responds to the contraction. Usually, a nerve conduction velocity (NCV) test (or nerve conduction study) is also performed at the same time as an EMG. This test consists of two electrodes being placed apart on the surface of the skin. One electrode is activated so that a muscle is electronically simulated. The second electrode senses the activity (electrical impulse) of the muscle as it moves. The NCV test measures the intensity and speed at which electrical signals pass between two points.

The EMG procedure is performed most often to help diagnose different diseases causing weakness. Although EMG is a test of the motor system, it may help identify abnormalities of nerves or spinal nerve roots that may be associated with pain or numbness. Other symptoms for which EMG may be useful include numbness, tingling, atrophy, stiffness, fasciculation (twitch), pain or cramping, deformity, and spasticity (abnormal muscle performance, such as muscle weakness). EMG results can help determine whether symptoms are due to a muscle disease or a neurological disorder, and, when combined with clinical findings, usually allow a confident diagnosis.

EMG can help diagnose many muscle and nerve disorders, including (but not restricted to) the following:

- muscular dystrophy or polymyositis
- congenital myopathies
- myasthenia gravis
- mitochondrial myopathies
- metabolic myopathies
- myotonias
- peripheral neuropathies
- radiculopathies
- nerve lesions
- amyotrophic lateral sclerosis
- polio
- spinal muscular atrophy
- Guillain-Barré syndrome
- ataxias
- myasthenias

Only a few special precautions are needed for this test. Patients with a history of bleeding disorder should consult with their treating physician before the test. Any person taking blood-thinning medications should inform the neurologist or other medical professional conducting the EMG procedure. A person with a pacemaker or other electrical medical device should inform the medical team of this before the procedure. If a muscle biopsy is planned as part of the diagnostic work-up, the EMG should not be performed at the same site, as it may effect the appearance of the muscle.

Preparation

Very few special preparations are needed before the EMG. Natural oils on the skin should be removed before the test. Therefore, take a shower or bath before the procedure. In addition, do not apply creams or lotions. The doctor supervising and interpreting the test should be given information about the symptoms, medical conditions, suspected diagnosis, neuroimaging studies, and other test results.

Aftercare

Minor bruising may occur after the procedure; it will fade over the next few days. Minor pain and bleeding may continue for several hours after the test. The muscle may be tender for a day or two. If any of these do not go away after several days, contact a medical professional. The doctor will not restrict activities after the test is completed under normal circumstances.

Results

The results of the test are available immediately upon completion of the EMG. However, a trained medical specialist, such as a neurologist, is needed to analyze and interpret the results.

Normal results

There should be some brief EMG activity during needle insertion. This activity may be increased in diseases of the nerve and decreased in long-standing muscle disorders where muscle tissue is replaced by fibrous tissue or fat. Muscle tissue normally does not show EMG activity when at rest or when moved passively by the examiner. When the patient actively contracts the muscle, spikes (motor unit action potentials) should appear on the recording screen, reflecting the electrical activity within. As the muscle is contracted more forcefully, more groups of muscle fibers are recruited or activated, causing more EMG activity.

Abnormal results

The interpretation of EMG results is not a simple matter, requiring analysis of the onset, duration, amplitude, and other characteristics of the spike patterns.

KEY TERMS

Motor neurons—Nerve cells that transmit signals from the brain or spinal cord to the muscles.

Motor unit action potentials—Spikes of electrical activity recorded during an EMG that reflect the number of motor units (motor neurons and the muscle fibers they transmit signals to) activated when the patient voluntarily contracts a muscle.

Risks

There are not significant risks in performing this procedure. The only minor risks occur when a needle is inserted under the skin. Such risks may include pain or discomfort, bleeding, bruising, or infection. Since medicine is not being injected under the skin, less pain is usually the case when compared to the insertion of a regular needle.

In addition, there is a minute risk for nerve injury when the needle is inserted under the skin. When such an electrode is inserted into the chest wall, a small risk is present that the puncture could cause air to leak into the cavity between the lungs and the chest wall. In such a case, a collapsed lung could result; although it is highly unlikely.

When the nerve conduction velocity test is performed, the patient will perceive a brief and very mild shock or tingling sensation.

Electrical activity at rest is abnormal; the particular pattern of firing may indicate denervation (for example, a nerve lesion, radiculopathy, or lower motor neuron degeneration), myotonia, or inflammatory myopathy.

Decreases in the amplitude and duration of spikes are associated with muscle diseases, which also show faster recruitment of other muscle fibers to compensate for weakness. Recruitment is reduced in nerve disorders.

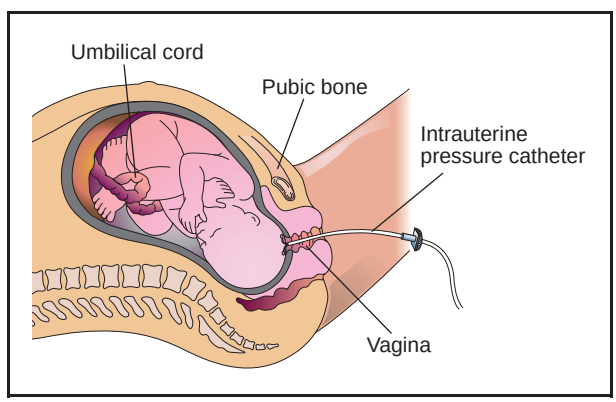
Electronic fetal monitoring

Definition

The electronic fetal monitor (EFM) is a device that records a fetus's heart rate and the presence or absence of the mother's uterine contractions.

Purpose

The EFM is used to assess fetal well being during routine prenatal visits. It is also used during labor and delivery when high-risk factors exist or when a clinical



Electronic fetal monitoring (EFM) is performed late in pregnancy or continuously during labor to ensure normal delivery of a healthy baby. EFM can be utilized either externally or internally in the womb. *(Illustration by Electronic Illustrators Group. © Cengage Learning®.)*

WWW.BOOKBAZ.IR

condition develops beforehand that places the fetus at risk. High-risk factors for EFM during labor include:

- low gestational age
- high maternal age
- placenta or cord problems
- meconium in the amniotic fluid
- maternal hypertension
- protein in the urine (proteinuria)

A fetus having trouble in labor often exhibits characteristic changes in heart rate after a contraction (late decelerations). Trouble also is indicated by significant slowing of the heart rate during a contraction (variable deceleration). If the fetus is not receiving enough oxygen to withstand the **stress** of labor, and delivery is many hours away, a **cesarean section** (C-section) may be necessary.

Description

The monitor produces a continuous paper record of the fetal heart rate (FHR) and records uterine contractions. FHR is captured on the top part of the paper printout; uterine activity, when monitored, appears on the lower part of the tracing.

Electronic fetal monitoring can be performed externally or internally. The external **ultrasound** approach is non-invasive and uses sensors (electrodes) placed on the mother's abdomen with an elastic belt. Another belt holds the contraction monitor.

External electronic fetal monitoring includes a non-stress test, which measures fetal heart rate (FHR) accelerations with normal movement of the fetus. Sometimes the fetal movement is encouraged by giving the mother a small meal or something to drink. Fetal acoustic stimulation and moving the fetus by rubbing the abdomen gently also may be used.

Two contraction stress tests, which measure the placenta's ability to provide enough oxygen to the fetus during pressure, are also used with electronic fetal monitoring. The nipple stimulation contractions **stress test** involves the mother self-stimulating her nipple while contractions and FHR are monitored. Another test, called oxytocin stimulation, involves the administration of the hormone oxytocin intravenously until three uterine contractions are observed within ten minutes, during which time the FHR is monitored.

Sometimes, it is difficult to hear the fetus's heartbeat with the monitoring device. Other times, the monitor may show subtle signs of a developing problem. In either case, the physician may recommend the use of an internal monitor, which provides a more accurate record of the fetus's heart rate. The internal monitor (or fetal scalp electrode) uses an electrode attached to the fetus's scalp through the cervix during an internal vaginal exam. The internal monitor can only be used when the cervix is dilated. In complicated pregnancies, continuous EFM is recommended during labor.

Benefits

Electronic fetal monitoring allows the physician to judge the well being of the fetus before and during delivery. Should the fetus appear to be in distress, the physician can recommend immediate delivery via cesarean section. EFM also allows an evaluation of the strength of the mother's contractions. Should labor not be progressing normally, medical intervention can be ordered.

Precautions

In general, no risks are associated with external fetal monitoring. However, the test can initiate labor and is generally not given to mothers at risk for preterm labor or with a condition that requires a cesarean section. Internal monitoring poses risks associated with improper placement of the electrodes. Some data suggest that EFM leads to unnecessary cesarean sections. Another drawback includes loss of maternal mobility when used during labor, which may slow labor.

Preparation

There are no special preparations required for external fetal monitoring. Preparation for placement of an internal scalp lead (ISL) is the same as for a routine vaginal exam.

Aftercare

No special subsequent care is required for electronic fetal monitoring.

Risks

Fetal monitoring is not a perfect test. Fetal assessment in labor is subject to differences in interpretation and consequent intervention; therefore, institutional policies and procedures should be followed.

Results

The normal fetal heart rate ranges from 120 to 160 beats per minute (bpm). Just as an adult's heart rate increases with movement, FHR increases when the fetus moves. A reactive heart rate tracing (also known

KEY TERMS

Cesarean section—Also called a C-section; delivery of a baby through an incision in the mother's abdomen instead of through the vagina.

Late deceleration—Transient slowing of the fetal heart (brachycardia), which reaches its height more than 30 seconds after the peak of the uterine contraction and may indicate the fetus is not receiving enough oxygen (hypoxia).

Non-stress test—A record of the fetal heart rate in the absence of contractions (stress).

Reactive stress test—A positive sign of fetal well being. The FHR rises at least 20 beats per minute above the baseline heart rate for at least 20 seconds, occurring at least twice in a 20-minute period.

Variable deceleration—Fetal bradycardia below 100 beats per minute denoting compression of the umbilical cord at the height of a uterine contraction.

as a reactive non-stress test, or NST) is considered a positive sign of fetal well being. A non-reactive NST may or may not imply fetal well being. The monitor strip is considered to be reactive when the FHR rises at least 15 to 20 bpm above the baseline heart rate for at least 20 seconds. This must occur at least twice in a 20-minute period.

Results are considered abnormal if the FHR drops below 120 or rises above 160 for sustained periods. In either of these cases the fetus may be exhibiting fetal distress. A mean FHR of less than 110 bpm may indicate bradycardia (slow heart beat). A mean FHR of over 160 bpm may indicate a tachycardia (rapid beating of the heart). However, some babies who are having problems may not exhibit such clear signs.

During a contraction, the flow of oxygen from the mother through the placenta to the fetus is temporarily stopped. It is as if the fetus has to hold its breath during each contraction. Both the placenta and the fetus are designed to withstand this condition. Between contractions, the fetus should be receiving more than enough oxygen to do well during the contraction.

One sign that a fetus is not getting enough oxygen between contractions is a drop in the FHR after the contraction (late deceleration). The heart rate recovers to a normal level between contractions, only to drop again after the next contraction. This is a subtler sign of distress. Trouble is also indicated by significant slowing during a contraction (variable decelerations).

Training and certification

Electronic fetal monitoring is primarily conducted by specialists in obstetrics and gynecology. Qualified registered nurses and advanced practice nurses may assist in or conduct electronic fetal monitoring.

Applying the external monitor is simple, but requires practice in the proper placement of the monitoring devices. The interpretation of the tracings requires continued vigilance in education and clinical practice. Training should include instruction electronic FHR monitoring and evaluation of uterine activity.

Electrophysiology study of the heart

Definition

An electrophysiology (EP) study of the heart is a nonsurgical analysis of the electrical conduction system (normal or abnormal) of the heart. The test employs cardiac catheters and sophisticated computers to generate electrocardiogram (EKG) tracings and electrical measurements with exquisite precision from within the heart chambers.

WWW.BOOKBAZ.IR

An electrophysiologist nurse monitors a patient's heart rhythm during an electrophysiology study for tachycardia. *(Collette Placek.)*

The EP study can be performed solely for diagnostic purposes. It also is performed to pinpoint the exact location of electrical signals (cardiac mapping) in conjunction with a therapeutic procedure called **catheter ablation**.

The test is simple, not painful, and performed in a special laboratory under controlled clinical circumstances by cardiologists and nurses who subspecialize in electrophysiology.

Purpose

A cardiologist may recommend an EP study when the standard EKG, Holter monitor, event recorder, **stress test**, echocardiogram, or angiogram cannot provide enough information to evaluate an abnormal heart rhythm, called an arrhythmia.

An EP study also may be beneficial in diagnosing a suspected arrhythmia in a patient who shows symptoms of an arrhythmia but in whom it could not be detected from other tests.

The purpose and great value of an EP study is that it offers more detailed information to the doctor about the electrical activity in the heart than the aforementioned noninvasive tests because electrodes are placed directly on heart tissue. This allows the electrophysiologist to determine the specific location of an arrhythmia and, oftentimes, correct it during the same procedure. This corrective treatment is permanent and considered a cure, and, in many cases, the patient may not need to take heart medications.

EP studies may be helpful in assessing:

- certain tachycardias or bradycardias of unknown cause
- patients who have been resuscitated after experiencing sudden cardiac death
- various symptoms of unknown cause, such as chest pain, shortness of breath, fatigue, or syncope (dizziness/fainting)
- response to anti-arrhythmic therapy

Precautions

Pregnant patients should not undergo an EP study because of exposure to radiation during the study, which may be harmful to the growing baby.

Patients who have **coronary artery disease** may need to have that treated before having an EP study.

Description

The rhythmic pumping action of the heart, which is essentially a muscle, is the result of electrical impulses traveling throughout the walls of the four heart chambers. These impulses originate in the sinoatrial (SA) node, which are specialized cells situated in the top right chamber of the heart: the right atrium. Normally, the SA node, acting like a spark plug, spontaneously generates the impulses, which travel through specific pathways throughout the atria to the atrioventricular (AV) node. The AV node is a relay station, sending the impulses to more specialized muscle fibers throughout the bottom chambers of the heart: the ventricles. If these pathways become damaged or blocked or if extra (abnormal) pathways exist, the heart's rhythm may be altered (perhaps too slow, too fast, or irregular), which can seriously affect the heart's pumping ability.

The patient is transported to the x-ray table in the EP lab and connected to various monitors. Sterile sheets are placed over him or her. A minimum of two catheters are inserted into the right femoral (thigh) vein in the groin area. Depending on the type of arrhythmia, the number of catheters used in an EP test and their route to the heart may vary. For certain tachycardias, two more catheters may be inserted in the left groin and one in the internal jugular (neck) vein or in the subclavian (below the clavicle) vein. The catheters are about 0.08 in (2 mm) in diameter, about the size of a spaghetti noodle. The catheters used in catheter ablation are slightly larger.

With the help of fluoroscopy (x rays on a television screen), all the catheters are guided to several specific locations in the heart. Typically, four to 10 electrodes are located on the end of the catheters, which have the ability to send electrical signals to stimulate the heart (called pacing) and to receive electrical signals from the heart—but not at the same time (just as a walkie-talkie cannot send and receive messages at the same time).

First, the electrodes are positioned to receive signals from inside the heart chambers. This allows the doctor to measure how fast the electrical impulses travel currently in the patient's heart. These measurements are called the patient's baseline measurements. Next, the electrodes are positioned to pace: The EP team actually tries to induce (sometimes in combination with various heart drugs) the arrhythmia that the patient has previously experienced so the team can observe it in a controlled environment, compare it to the patient's clinical or spontaneous arrhythmia, and decide how to treat it.

Once the arrhythmia is induced and the team determines it can be treated with catheter ablation, cardiac mapping is performed to locate precisely the origin and route of the abnormal pathway. When this is accomplished, the ablating electrode catheter is positioned directly against the abnormal pathway, and high radio-frequency energy is delivered through the electrode to destroy (burn) the tissue in this area.

Preparation

The following preparations are made for an EP study:

- the patient may be advised to stop taking certain medications, especially heart drugs, that may interfere with the test results
- blood tests usually are ordered the week before the test
- the patient undergoes conscious sedation (awake but relaxed) during the test. This is accomplished quite often with the anesthetic drugs VersedR (Roche laboratories) and fentanyl
- a local anesthetic is injected at the site of catheter insertion

Aftercare

The patient needs to rest flat in bed for several hours after the procedure to allow healing at the catheter insertion sites.

The patient often returns home either the same day of the test or the next day. Someone should drive him or her home.

The doctor may prescribe drugs and/or insert an AFCD to treat the arrhythmia and may do a possible follow-up EP study.

Risks

The EP diagnostic study and catheter ablation are low-risk procedures. There is a small risk of bleeding and/or infection at the site of catheter insertion, but this occurs less than 1% of the time. Blood clot formation occurs only two in 1,000 instances and is minimized with blood thinner medications

WWW.BOOKBAZ.IR

KEY TERMS

Ablation—Remove or destroy, such as by burning or cutting.

Angiogram—X ray of a blood vessel after special x-ray dye has been injected into it.

Bradycardia—Slow heartbeat.

Cardiac catheter—Long, thin, flexible tube that is threaded into the heart through a blood vessel.

Cardiologist—Doctor who specializes in diagnosing and treating heart diseases.

Echocardiogram—Ultrasound image of the heart.

Electrocardiogram—Tracing of the electrical activity of the heart.

Electrode—Medium for conducting an electrical current—in this case, platinum wires.

Electrophysiology—Study of how electrical signals in the body relate to physiologic function.

Event recorder—A small machine, worn by a patient usually for several days or weeks, that is activated by the patient to record his or her EKG when a symptom is detected.

Fibrillation—Rapid, random contraction (quivering).

Holter monitor—A small machine, worn by a patient usually for 24 hours, that continuously records the patient's EKG during usual daily activity.

Stress test—Recording a patient's EKG during exercise.

Supraventricular tachycardia—A fast heart beat that originates above the ventricles.

Tachycardia—Fast heartbeat.

Vascular—Pertaining to blood vessels.

administered during the procedure. Vascular injuries causing hemorrhage or **thrombophlebitis** are possible but occur less than 0.7% of the time. Cardiac perforations occur only in one or two per 1,000 instances. If the right internal jugular vein is accessed, the small possibility of puncturing the lung with the catheter exists, which, at worst, could cause a collapsed lung.

Because **ventricular tachycardia** or fibrillation (lethal **arrhythmias**) may be induced in the patient, the EP lab personnel must be prepared to defibrillate the patient as necessary.

Results

A normal result would be that the heart initiates and conducts electrical impulses normally.

An abnormal result would be confirmation of arrhythmias, such as:

- supraventricular tachycardias
- ventricular arrhythmias
- accessory (extra) pathways
- bradycardias

Elephantiasis

Definition

The word elephantiasis is a vivid and accurate term for the syndrome it describes: the gross (visible) enlargement of the arms, legs, or genitals to elephantoid size.

Description

True elephantiasis is the result of a parasitic infection caused by three specific kinds of round worms. The long, threadlike worms block the body's lymphatic system—a network of channels, lymph nodes, and organs that helps maintain proper fluid levels in the body by draining lymph from tissues into the bloodstream. This blockage causes fluids to collect in the tissues, which can lead to great swelling, called "lymphedema." Limbs can swell so enormously that they resemble an elephant's foreleg in size, texture, and color. This is the severely disfiguring and disabling condition of elephantiasis.

Man suffering from elephantiasis. *(© C. James Webb/ Phototake.—All rights reserved.)*

There are a few different causes of elephantiasis, but the agents responsible for most of the elephantiasis in the world are filarial worms: white, slender round worms found in most tropical and subtropical places. They are transmitted by particular kinds (species) of mosquitoes, that is, bloodsucking insects. Infection with these worms is called "lymphatic filariasis" and over a long period of time can cause elephantiasis.

Lymphatic **filariasis** is a disease of underdeveloped regions found in South America, Central Africa, Asia, the Pacific Islands, and the Caribbean. It is a disease that has been present for centuries, as ancient Persian and Indian writings clearly described elephant-like swellings of the arms, legs, and genitals. It is estimated that 120 million people in the world have lymphatic filariasis. The disease appears to be spreading, in spite of decades of research in this area.

Other terms for elephantiasis are Barbados leg, elephant leg, morbus herculeus, mal de Cayenne, and myelolymphangioma.

Other situations that can lead to elephantiasis are:

- a protozoan disease called leishmaniasis
- a repeated streptococcal infection
- the surgical removal of lymph nodes (usually to prevent the spread of cancer)
- a hereditary birth defect

Causes and symptoms

Three kinds of round worms cause elephantiasis filariasis: *Wuchereria bancrofti*, *Brugia malayi*, and *Brugia timori*. Of these three, *W. bancrofti* makes up about 90% of the cases. Humans are the only known host of *W. bancrofti*.

Culex, *Aedes*, and *Anopheles* mosquitoes are the carriers of *W. bancrofti*. *Anopheles* and *Mansonia* mosquitoes are the carriers of *B. malayi*. In addition, *Anopheles* mosquitoes are the carriers of *B. timori*.

Infected female mosquitoes take a blood meal from a human, and in doing so, introduce larval forms of the particular parasite they carry to the person. These larvae migrate toward a lymphatic channel, then travel to various places within the lymphatic system, usually positioning themselves in or near lymph nodes throughout the body. During this time, they mature into more developed larvae and eventually into adult worms. Depending upon the species of round worm, this development can take a few months or more than a year. The adult worms grow to about 1 in (2.5 cm) to 4 in (10 cm) long.

The adult worms can live from about three to eight years. Some have been known to live to 20 years, and in one case 40 years. The adult worms begin reproducing numerous live embryos, called microfilariae. The microfilariae travel to the bloodstream, where they can be ingested by a mosquito when it takes a blood meal from the infected person. If they are not ingested by a mosquito, the microfilariae die within about 12 months. If they are ingested by a mosquito, they continue to mature. They are totally dependent on their specific species of mosquito to develop further. The cycle continues when the mosquito takes another blood meal.

Most of the symptoms an infected person experiences are due to the blockage of the lymphatic system by the adult worms and due to the substances (excretions and secretions) produced by the worms.

WWW.BOOKBAZ.IR

The body's allergic reactions may include repeated episodes of **fever**, shaking chills, sweating, headaches, **vomiting**, and **pain**. Enlarged lymph nodes, swelling of the affected area, skin **ulcers**, bone and joint pain, tiredness, and red streaks along the arm or leg also may occur. Abscesses can form in lymph nodes or in the lymphatic vessels. They may appear at the surface of the skin as well.

Long-term infection with lymphatic filariasis can lead to **lymphedema**, hydrocele (a buildup of fluid in any saclike cavity or duct) in the scrotum, and elephantiasis of the legs, scrotum, arms, penis, breasts, and vulvae. The most common site of elephantiasis is the leg. It typically begins in the ankle and progresses to the foot and leg. At first the swollen leg may feel soft to the touch but eventually becomes hard and thick. The skin may appear darkened or warty and may even crack, allowing bacteria to infect the leg and complicate the disease. The microfilariae usually do not cause injury. In some instances, they cause "eosinophilia," an increased number of eosinophils (a type of white blood cells) in the blood.

This disease is more intense in people who never have been exposed to lymphatic filariasis than it is in the native people of tropical areas where the disease occurs. This is because many of the native people often are immunologically tolerant.

Diagnosis

The only sure way to diagnose lymphatic filariasis is by detecting the parasite itself, either the adult worms or the microfilariae.

Microscopic examination of the person's blood may reveal microfilariae. But many times, people who have been infected for a long time do not have microfilariae in their bloodstream. The absence of them, therefore, does not mean necessarily that the person is not infected. In these cases, examining the urine or hydrocele fluid or performing other clinical tests is necessary.

Collecting blood from the individual for microscopic examination should be done during the night when the microfilariae are more numerous in the bloodstream. (Interestingly, this is when mosquitoes bite most frequently.) During the day microfilariae migrate to deeper blood vessels in the body, especially in the lung. If it is decided to perform the blood test during the day, the infected individual may be given a "provocative" dose of medication to provoke the microfilariae to enter the bloodstream. Blood then can be collected an hour later for examination.

Detecting the adult worms can be difficult because they are deep within the lymphatic system and difficult to get to. Biopsies usually are not performed because they usually do not reveal much information.

Treatment

The drug of choice in treating lymphatic filariasis is diethylcarbamazine (DEC). The trade name in the United States is Hetrazan.

The treatment schedule is typically 2 mg/kg per day, three times a day, for three weeks. The drug is taken in tablet form.

DEC kills the microfilariae quickly and injures or kills the adult worms slowly, if at all. If all the adult worms are not killed, remaining paired males and females may continue to produce more larvae. Therefore, several courses of DEC treatment over a long time period may be necessary to rid the individual of the parasites.

DEC has been shown to reduce the size of enlarged lymph nodes and, when taken long-term, to reduce elephantiasis. In India, DEC has been given in the form of a medicated salt, which helps prevent spread of the disease.

The side effects of DEC almost all are due to the body's natural allergic reactions to the dying parasites rather than to the DEC itself. For this reason, DEC must be given carefully to reduce the danger to the individual. Side effects may include fever, chills, **headache**, **dizziness**, **nausea and vomiting**, **itching**, and joint pain. These side effects usually occur within the first few days of treatment. These side effects usually subside as the individual continues taking the drug.

There is an alternate treatment plan for the use of DEC. This plan is designed to kill the parasites slowly (to reduce allergic reactions to the dead microfilariae and dying adult worms within the body). Lower doses of DEC are taken for the first few days, followed by the higher dose of 2 mg/kg per day for the remaining three weeks. In addition, **steroids** may be prescribed to prevent the individual's body from reacting severely to the dead worms.

Another drug used is Ivermectin. Early research studies of Ivermectin show that it is excellent in killing microfilariae, but the effects of this drug on the adult worms are still being investigated. It is probable that patients will need to continue using DEC to kill the adult worms. Mild side effects of Ivermectin include headache, fever, and myalgia.

Other means of managing lymphatic filariasis are pressure bandages to wrap the swollen limb and elastic

KEY TERMS

Antigen—Any substance (usually a protein) that causes an immune response by the body to produce antibodies.

Filarial—Threadlike. The word "filament" is formed from the same root word.

Host—A person or animal in which a parasite lives, is nourished, grows, and reproduces.

Lymph—A watery substance that collects in the tissues and organs of the body and eventually drains into the bloodstream.

Lymphatic system—A network composed of vessels, lymph nodes, the tonsils, the thymus gland, and the spleen. It is responsible for transporting fluid and nutrients to the bloodstream and for maturing certain blood cells that are part of the body's immune system.

Lymphedema—The unnatural accumulation of lymph in the tissues of the body, which results in swelling in that area.

Protozoa—(Plural form of protozoan) Single-celled organisms (not bacteria) of which about 30 kinds cause disease in humans.

Streptococcal—Pertaining to any of the *Streptococcus* bacteria. These organisms can cause pneumonia, skin infections, and many other diseases.

stockings to help reduce the pressure. Exercising and elevating a bandaged limb also can help reduce its size.

Surgery can be performed to reduce elephantiasis by removing excess fatty and fibrous tissue, draining the swelled area, and removing the dead worms.

Prognosis

With DEC treatment, the prognosis is good for early and mild cases of lymphatic filariasis. The prognosis is poor, however, for heavy parasitic infestations.

Prevention

The two main ways to control this disease are to take DEC preventively, which has shown to be effective, and to reduce the number of carrier insects in a particular area.

Avoiding mosquito bites with insecticides and insect repellents is helpful, as is wearing protective clothing and using bed netting.

Much effort has been made in cleaning the breeding sites (stagnant water) of mosquitoes near people's homes in areas where filariasis is found.

Before visiting countries where lymphatic filariasis is found, it would be wise to consult a travel physician to learn about current preventative measures.

Embolism

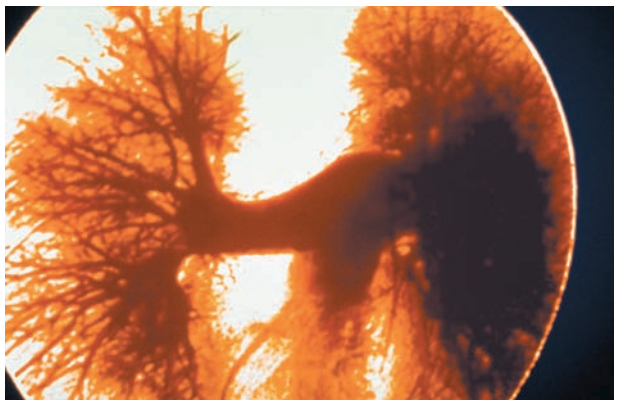
Definition

An embolism is an obstruction in a blood vessel due to a blood clot or other foreign matter that gets stuck while traveling through the bloodstream. The plural of embolism is emboli.

Description

Emboli have moved from the place where they were formed through the bloodstream to another part of the body, where they obstruct an artery and block the flow of blood. The emboli are usually formed from **blood clots** but are occasionally comprised of air, fat, or tumor tissue. Embolic events can be multiple and small, or single and massive. They can be life-threatening and require immediate emergency medical care. There are three general categories of emboli: arterial, gas, and pulmonary. Pulmonary emboli are the most common.

WWW.BOOKBAZ.IR



A close-up view of a pulmonary embolism. *(Custom Medical Stock Photo, Inc.)*

Arterial embolism

In arterial emboli, blood flow is blocked at the junction of major arteries, most often at the groin, knee, or thigh. Arterial emboli are generally a complication of **heart disease**. An **arterial embolism** in the brain (cerebral embolism) causes **stroke**, which can be fatal. An estimated 5–14% of all strokes are caused by cerebral emboli. Arterial emboli to the extremities can lead to tissue death and **amputation** of the affected limb if not treated effectively within hours. Intestines and kidneys can also be damaged by emboli.

Gas embolism

Gas emboli result from the compression of respiratory gases into the blood and other tissues due to rapid changes in environmental pressure, for example, while flying or scuba diving. As external pressure decreases, gases (like nitrogen) that are dissolved in the blood and other tissues become small bubbles that can block blood flow and cause organ damage.

Pulmonary embolism

In a **pulmonary embolism**, a common illness, blood flow is blocked at a pulmonary artery. When emboli block the main pulmonary artery, and in cases where there are no initial symptoms, a pulmonary embolism can quickly become fatal. According to the American Heart Association, an estimated 600,000 Americans develop pulmonary emboli annually and 60,000 die from it.

A pulmonary embolism is difficult to diagnose. Less than 10% of patients who die from a pulmonary embolism were diagnosed with the condition. More than 90% of cases of pulmonary emboli are complications of **deep vein thrombosis**, blood clots in the deep vein of the leg or pelvis.

Causes and symptoms

Arterial emboli are usually a complication of heart disease where blood clots form in the heart's chambers. Gas emboli are caused by rapid changes in environmental pressure that could happen when flying or scuba diving. A pulmonary embolism is caused by blood clots that travel through the blood stream to the lungs and block a pulmonary artery. More than 90% of the cases of pulmonary embolism are a complication of deep vein thrombosis, which typically occurs in patients who have had **orthopedic surgery** and patients with cancer or other chronic illnesses like **congestive heart failure**.

Risk factors for arterial and pulmonary emboli include: prolonged bed rest, surgery, **childbirth**, **heart attack**, stroke, congestive **heart failure**, cancer, **obesity**, a broken hip or leg, **oral contraceptives**, sickle cell anemia, chest **trauma**, certain congenital heart defects, and old age. Risk factors for gas emboli include: scuba diving, amateur plane flight, **exercise**, injury, obesity, **dehydration**, excessive alcohol, colds, and medications such as **narcotics** and **antihistamines**.

Symptoms of an arterial embolism include:

- severe pain in the area of the embolism
- pale, bluish cool skin
- numbness
- tingling
- muscular weakness or paralysis

Common symptoms of a pulmonary embolism include:

- labored breathing, sometimes accompanied by chest pain
- a rapid pulse
- a cough that may produce sputum
- a low-grade fever
- fluid build-up in the lungs

Less common symptoms include:

- coughing up blood
- pain caused by movement or breathing
- leg swelling
- bluish skin
- fainting
- swollen neck veins

Diagnosis

An embolism can be diagnosed through the patient's history, a physical exam, and diagnostic tests. The use of various tests may change, as physicians and clinical guidelines evaluate the most effective test in terms of accuracy and cost. For arterial emboli, cardiac **ultrasound** and/or arteriography are ordered. For a pulmonary embolism, a chest x ray, lung scan, pulmonary **angiography**, **electrocardiography**, arterial blood gas measurements, and **venography** or venous ultrasound could be ordered.

Diagnosing an arterial embolism

Ultrasound uses sound waves to create an image of the heart, organs, or arteries. The technologist applies gel to a hand-held transducer, then presses it against the patient's body. The sound waves are converted into an image that can be displayed on a monitor. Performed in an outpatient diagnostic laboratory, the test takes 30–60 minutes.

An arteriogram is an x ray in which a contrast medium is injected to make the arteries visible. It can be performed in a **radiology** unit, outpatient clinic, or diagnostic center of a hospital.

Diagnosing a pulmonary embolism

A chest x ray can show fluid build-up and detect other respiratory diseases. The perfusion lung scan shows poor flow of blood in areas beyond blocked arteries. The patient inhales a small amount of radiopharmaceutical and pictures of airflow into the lungs are taken with a gamma camera. Then a different radiopharmaceutical is injected into an arm vein and lung blood flow is scanned. A normal result essentially rules out a pulmonary embolism. A lung scan can be performed in a hospital or an outpatient facility and takes about 45 minutes.

Pulmonary angiography is one of the most reliable tests for diagnosing a pulmonary embolism. Pulmonary angiography is a radiographic test that involves injection of a radio contrast agent to show the pulmonary arteries. A cinematic camera records the blood flow through the patient, who lies on a table. Pulmonary angiography is usually performed in a hospital's radiology department and takes 30–60 minutes.

An electrocardiograph shows the heart's electrical activity and helps distinguish a pulmonary embolism from a heart attack. Electrodes covered with conducting jelly are placed on the patient's chest, arms, and legs. Impulses of the heart's activity are traced on paper. The test takes about 10 minutes.

Arterial blood gas measurements are sometimes helpful but, alone, they are not diagnostic for pulmonary embolism. Blood is taken from an artery instead of a vein, usually in the wrist.

Venography is used to look for the most likely source of a pulmonary embolism, deep vein thrombosis. It is very accurate, but it is not used often, because it is painful, expensive, exposes the patient to a fairly high dose of radiation, and can cause complications. Venography identifies the location, extent, and degree of attachment of the blood clots and enables the condition of the deep leg veins to be assessed. A contrast solution is injected into a foot vein through a catheter. The physician observes the movement of the solution through the vein with a fluoroscope while a series of x rays are taken. Venography takes 30–45 minutes and can be done in a physician's office, a laboratory, or a hospital. Radionuclide venography, in which a radioactive isotope is injected, is occasionally used, especially if a patient has had reactions to contrast solutions. Venous ultrasound is the preferred evaluation of leg veins.

As noninvasive methods such as high-speed computed tomography (CT) scanning improve, they may be used to diagnose emboli. For instance, spiral (also called helical) CT scans may be the preferred tool for diagnosing pulmonary embolism in pregnant women.

Treatment

Patients with emboli require immediate hospitalization. They are generally treated with clot-dissolving and/or clot-preventing drugs. **Thrombolytic therapy** to dissolve blood clots is the definitive treatment for a severe pulmonary embolism. Streptokinase, urokinase, and recombinant tissue plasminogen activator (TPA) are used. Heparin has been the anticoagulant drug of choice for preventing formation of blood clots. A new drug has been approved for treatment of acute pulmonary emboli. Called fondaparinux (Arixtra), it usually is administered with Warfarin, an oral anticoagulant. Warfarin is sometimes used with other drugs to treat acute embolism events and is usually continued after the hospitalization to help prevent future emboli. Arixtra also has been used on an ongoing basis to prevent pulmonary emboli.

In the case of an arterial embolism, the affected limb is placed in a dependent position and kept warm. Embolectomy is the treatment of choice in the majority of early cases of arterial emboli in the extremities.

WWW.BOOKBAZ.IR

In this procedure, a balloon-tipped catheter is inserted into the artery to remove thromboembolic matter.

With a pulmonary embolism, **oxygen therapy** is often used to maintain normal oxygen concentrations. For people who can not take anticoagulants and in some other cases, surgery may be needed to insert a device that filters blood returning to the heart and lungs.

Prognosis

Of patients hospitalized with an arterial embolism, 25–30% die, and 5–25% require amputation of a limb. About 10% of patients with a pulmonary embolism die suddenly within the first hour of onset of the condition. The outcome for all other patients is generally good; only 3% of patients die who are properly diagnosed early and treated. In cases of an undiagnosed pulmonary embolism, about 30% of patients die.

Prevention

Embolism can be prevented in high risk patients through antithrombotic drugs such as heparin, venous interruption, gradient elastic stockings, and intermittent pneumatic compression of the legs. The combination of graduated compression stockings and low-dose heparin is significantly more effective than low-dose heparin alone.

Gradient elastic stockings, also called anti-embolism stockings, decrease the risk of blood clots by compressing superficial leg veins and forcing blood into the deep veins. They can be knee-, thigh-, or waist-length. Many physicians order the use of stockings before surgery and until there is no longer an elevated risk of developing blood clots. The risk of deep vein thrombosis after surgery is reduced 50% with the use of these stockings. The American Heart Association recommends that the use of graduated compression stockings be considered for all high-risk surgical patients.

Intermittent pneumatic compression involves wrapping knee- or thigh-high cuffs around the legs to prevent blood clots. The cuffs are connected to a pump that inflates and deflates, mimicking the heart's normal pumping action and reducing the pooling of blood. Intermittent pneumatic compression can be used during surgery and recovery and continues until there is no longer an elevated risk of developing blood clots. The American Heart Association recommends the use of intermittent pneumatic compression for patients who cannot take anticoagulants, for example, spinal cord and brain trauma patients.

KEY TERMS

Anticoagulants—Drugs that suppress, delay, or prevent blood clots. Anticoagulants are used to treat embolisms.

Artery—A blood vessel that carries blood from the heart to other body tissues. Embolisms obstruct arteries.

Deep vein thrombosis—A blood clot in the calf's deep vein. This frequently leads to pulmonary embolism if untreated.

Emboli—Clots or other substances that travel through the blood stream and get stuck in an artery, blocking circulation.

Thrombolytics—Drugs that dissolve blood clots. Thrombolytics are used to treat embolisms.

Emergency contraception

Definition

Emergency **contraception** or emergency birth control uses either emergency contraceptive pills (ECPs) or a Copper-T **intrauterine device** (IUD) to help prevent **pregnancy** following unprotected vaginal intercourse.

Purpose

Emergency contraception may be used to prevent pregnancy after vaginal intercourse when:

- A birth control method was not used. Young people, in particular, may not be prepared for their first experience of sexual intercourse.
- A condom broke or slipped and ejaculation occurred within the woman's vagina.
- The male failed to withdraw from the vagina before ejaculation.
- A woman failed to take her birth control pills.
- A diaphragm, cap, or shield slipped out of place, followed by ejaculation within the vagina.
- A woman's "safe days" were miscalculated.
- A woman was raped or otherwise forced to have unprotected intercourse.

Women who missed taking their **oral contraceptives** may consider emergency contraception if:

- A new packet of pills was started at least two days late.
- Two to four of the first seven active (hormone-containing) pills (days 1–7) were missed.
- Five or more active pills were missed consecutively.

On average eight out of every 100 fertile women will become pregnant after having one episode of unprotected vaginal intercourse during the second or third week of their menstrual cycle. Following treatment with combined ECPs, only two of those 100 women will become pregnant—a 75% reduction. Following treatment with progestin-only ECPs, only one woman out of the 100 will become pregnant—an 89% reduction. Following emergency insertion of an IUD there is a 99.9% reduction in the risk of pregnancy.

Precautions

Emergency contraception does not work after the onset of pregnancy; nor should it be used as a regular method of birth control. ECPs do not prevent pregnancy from intercourse that occurs following the treatment; another birth control method must be used to prevent pregnancy. Although ECPs will not affect an existing pregnancy and will not harm the fetus, emergency contraception should not be used if a woman is already pregnant.

Frequent use of ECPs can result in irregular or unpredictable menstrual periods. Additional doses of ECPs usually do not reduce the risk of pregnancy and they increase the risk of side effects including **nausea and vomiting**.

Almost all women can use emergency contraception safely, even those who cannot use oral contraceptives as a regular method of birth control because of **heart disease**, **blood clots**, **stroke**, or other cardiovascular problems. The anti-convulsive medication Dilantin may reduce the effectiveness of ECPs. Some physicians recommend doubling the first of the two ECP doses if taken with Dilantin.

Progestin-only ECPs (POPs) are not recommended for women who:

- may be pregnant already
- have a hypersensitivity to any component of the medication
- have abnormal, undiagnosed genital bleeding

Copper-T IUDs should not be used for emergency contraception if a woman:

- is pregnant
- has a history of pelvic inflammatory disease (PID) that has impaired her fertility
- has one of numerous other conditions affecting her reproductive system
- has—or is currently at risk for contracting—a sexually transmitted disease (STD) such as HIV/AIDS, chlamydia, or gonorrhea, since IUD insertion can introduce infectious agents into the sterile uterine cavity

Those at risk for contracting an STD include women who:

- have been raped
- have had unprotected sex with a new partner
- are in a non-monogamous relationship
- use intravenous drugs
- have partners who use intravenous drugs

Description

Although emergency contraception—sometimes called post-coital or morning-after contraception—has been available for over a quarter of a century, almost one-half of the 6.3 million pregnancies in the United States each year are unintended. Among teen pregnancies 80% are unintentional. About one-half of unintended pregnancies are caused by contraceptive failure, either a failure of the method or a mistake by the user. The remainder of unintended pregnancies occurs because birth control was not employed. Emergency contraception could help prevent some of the 1.4 million abortions that take place in the United States every year.

Emergency contraception prevents pregnancy by one of the following methods:

- delaying or inhibiting ovulation—the release of eggs from the ovary

WWW.BOOKBAZ.IR

- altering the transport of the sperm or egg, thereby preventing fertilization of the egg by a sperm
- altering the endometrium or uterine lining, thereby preventing implantation—the attachment of the fertilized egg to the wall of the uterus

The mechanism by which ECPs prevent pregnancy depends on the stage of the woman's menstrual cycle. In most cases ECPs delay or inhibit ovulation and have no effect on implantation. IUDs used as emergency contraception appear to interfere with implantation of the fertilized egg; although they also may prevent fertilization, as they are thought to do when they are used as a regular method of birth control.

Emergency contraceptive pills (ECPs)

ECPs contain synthetic hormones that mimic the hormones produced by a woman's body. Many common brands of birth control pills can be used for emergency contraception even though they are not labeled for that use. Any of the first 21 pills in a regular 28-pill package of oral contraceptives can be used for emergency contraception. The last seven pills in 28-pill packs do not contain hormones. The number of pills that constitute an emergency contraceptive dose depends on the brand of pill. The same brand should be used for both doses of ECPs. Many ECPs are available outside of the United States, where they are packaged, labeled, and sold for emergency contraceptive purposes.

COMBINED ECPS. Combined ECPs available in the United States contain 100 mcg of the synthetic estrogen, ethinyl estradiol, and 0.5–0.6 mg of the synthetic progestin levonorgestrel per dose. Combined ECPs are taken according to the Yuzpe Regimen, named after A. Albert Yuzpe, the Canadian researcher who first demonstrated their safety and effectiveness in 1974. With the Yuzpe Regimen, the first dose of combined ECPs is taken as soon as possible after unprotected intercourse and the second dose is taken 12 hours later. The timing of the second dose can vary by a few hours without diminishing its effectiveness. The Preven Emergency Contraceptive Kit—the first product to be specifically labeled and marketed for emergency contraception—is no longer available.

Combined ECPs available in the United States include:

- Alesse, manufactured by Wyeth-Ayerst; five pink pills per dose
- Aviane, manufactured by Duramed; five orange pills per dose
- Cryselle, manufactured by Barr; four white pills per dose
- Enpresse from Barr; four orange pills per dose
- Lessina from Barr; five pink pills per dose
- Levlen from Berlex; four light orange pills per dose
- Levlite from Berlex; five pink pills per dose
- Levora from Watson; four white pills per dose
- Lo/Ovral from Wyeth-Ayerst; four white pills per dose
- Low-Ogestrel from Watson; four white pills per dose
- Lutera from Watson; five white pills per dose
- Nordette from Wyeth-Ayerst; four light orange pills per dose
- Ogestrel from Watson; two white pills per dose
- Ovral from Wyeth-Ayerst; two white pills per dose
- Portia from Barr; four pink pills per dose
- Seasonale from Barr; four pink pills per dose
- Tri-Levlen from Berlex; four yellow pills per dose
- Triphasil from Wyeth-Ayerst; four yellow pills per dose
- Trivora from Watson; four pink pills per dose

PROGESTIN-ONLY ECPS. Progestin-only ECPs (POPs) are prescribed frequently, particularly for women who cannot take estrogen or who are **breastfeeding**. POPs contain 0.75 mg of levonorgestrel per dose. They are equally effective regardless of whether the two doses are taken simultaneously or 12–24 hours apart. POPs are most effective if taken within 72 hours of unprotected intercourse; however they reduce the risk of pregnancy if taken within 120 hours.

Progestin-only pills include:

- Plan B from Barr is the only drug available in the United States that is specifically designed and designated as an ECP—one white pill per dose.
- Ovrette from Wyeth-Ayerth requires swallowing 20 yellow pills for each dose.

The Copper-T IUD

The Copper-T 380A IUD (ParaGard) is a T-shaped device that provides emergency contraception if inserted into the uterus by a healthcare provider within seven days after unprotected intercourse. It can be removed by the healthcare provider after the woman's next menstrual period begins or it can remain in place for up to 10–12 years as an effective method of birth control.

Availability

In most of the United States, emergency contraception requires a special prescription or a prescription for a monthly supply of an appropriate oral contraceptive. Most physicians do not routinely discuss the use of emergency contraception with their patients and some pharmacies refuse to carry ECPs.

Emergency contraception is available from:

- public and college health clinics
- women's health centers
- Planned Parenthood clinics
- private doctors
- hospital emergency rooms, except those affiliated with a religion that opposes the use of birth control
- pharmacists directly, in a small number of states

Some healthcare providers may prescribe ECPs over the telephone. Sexual assault victims may be offered ECPs in the hospital emergency room.

The circumstances under which emergency contraception may be used has long been a matter of controversy in the United States. In 1999, the U.S. Food and Drug Administration (FDA) approved the sale of a product known as Plan B by prescription. The whose primary ingredient in Plan B is levonorgestrel. Only four years later, however, the group planning to sell Plan B, Women's Capital Corporation (WCC), petitioned the FDA to allow sale of the drug on an over-the-counter (OTC) basis (without prescription). Only a few months later, a special advisory panel to the FDA recommended by a vote of 23 to 4 approval of the WCC petition. In such circumstances, the FDA almost invariably follows the recommendation of its advisory committee. Such was not to be the case, however, with Plan B. In May 2004, the FDA denied the WCC petition (which was now being pursued by the new owners of Plan B, Barr Pharmaceutical). When Barr appealed the FDA decision, the agency agreed to consider allowing OTC sale of the drug, but only to women over the age of 16, provided that Barr could provide solid evidence that it was was to do so. The debate between the FDA and proponents of OTC sale of Plan B (and other emergency contraceptives) continued over the next decade. Finally, in 2013, Federal judge Edward Korman issued a stern warning to the FDA that it could no longer ignore his previous rulings and that it had to permit OTC sale of Plan B to women of all ages without prescription.

Costs

The cost of emergency contraception varies greatly according to region and location and any additional required services. Family-planning clinics and public healthcare centers may provide lower-cost emergency contraception or charge according to an income-based sliding scale.

Estimated costs for emergency contraception are:

- $8–$35 for Plan B
- $20–$50 for combined ECPs
- $50–$70 for other progestin-only ECPs
- $35–$150 for a visit to a healthcare provider
- $10–$20 for a pregnancy test
- about $400 for an exam, IUD, and insertion; however the IUD can remain in place for up to 12 years

Preparation

For emergency contraception to be effective, it must be used as soon as possible following unprotected intercourse. Some healthcare providers and women's health centers prescribe or supply packets of ECPs—called EC-to-Go—so that they are available immediately if required. Supplies of ECPs are particularly important for women who are at high risk for having unprotected intercourse. EC-to-Go also avoids the cost of an extra visit to a healthcare provider.

Studies have found that neither the use of ECPs, nor having a supply of ECPs on hand, reduce the likelihood that women, including teenagers, will use conventional contraceptive methods. In fact it has been shown that the use of ECPs often increases the likelihood that a regular birth control method will be employed.

If an office visit is required, a healthcare provider may take a medical history, perform a pregnancy test on a urine sample, and—provided that pregnancy has not occurred—discuss the appropriate type of emergency contraception.

Aftercare

For about 10–15% of women who take ECPs, the timing, duration, and/or amount of bleeding for their next menstrual period may be different than usual. About 50% of women have their first post-ECP menstrual period one to three days earlier or later than expected. Most often it is earlier than expected. Bleeding may be normal or heavier, lighter, or more spotty than usual.

Following IUD insertion, a woman may need to be escorted or driven home and she may require rest.

WWW.BOOKBAZ.IR

Risks

Emergency contraception is considered to be both safe and effective for teenagers as well as adult women. However, emergency contraception may not prevent an ectopic pregnancy—a pregnancy outside of the uterus, in the fallopian tubes or abdomen. Ectopic pregnancies are medical emergencies and can be fatal.

Side effects of ECPs

About 50% of women feel sick to their stomachs for approximately 24 hours after taking combined ECPs. Nausea occurs in 30–50% of women and 15–25% of women experience **vomiting**. Only 23% of women who take progestin-only ECPs experience nausea and only 6% have vomiting.

If vomiting occurs within one hour of taking ECPs, the dose may have to be repeated. OTC medications such as Dramamine II, Bonine, or their generic equivalents, taken one hour before the ECPs, reduce the risk of nausea and vomiting, although they may cause drowsiness. Two 25-mg tablets of Meclizine, taken one hour before the ECPs, reduce the risk of nausea by 27% and the risk of vomiting by 64%; however, there is about a 30% risk of drowsiness. If vomiting occurs after the first dose of an ECP, antinausea medication should be taken one hour before the second dose. The second dose also may be taken as a vaginal suppository by placing the pills as far as possible into the vagina for absorption through the vaginal tissue.

Other side effects of ECPs can include:

- breast tenderness
- abdominal pain
- irregular bleeding
- dizziness
- headaches
- fatigue

Side effects usually last only one to two days and are far less frequent with progestin-only ECPs as compared with combined ECPs.

Side effects of IUD insertion

Side effects of IUD insertion may include:

- abdominal discomfort
- vaginal bleeding or spotting
- infection

The risk of pelvic infection is very small among women who are not at risk for STDs.

KEY TERMS

Emergency contraceptive pills; ECPs—Medication containing synthetic hormones for preventing pregnancy after unprotected vaginal intercourse.

Endometrium—The lining of the uterus.

Ethinyl estradiol—A semi-synthetic derivative of estradiol—an estrogen or female sex hormone—used in birth control pills and combined ECPs.

Implantation—The embedding of a fertilized egg in the inner wall of the uterus.

Intrauterine device; IUD—A device inserted into the uterus to prevent pregnancy.

Levonorgestrel—A synthetic progestin used in ECPs.

Ovulation—The discharge of an ovum (egg) from the mature follicle of the ovary.

Progestin—A synthetic or natural drug that acts on the uterine lining.

Yuzpe Regimen—A two-dose treatment with combined ECPs to prevent pregnancy after unprotected intercourse; the first dose is taken as soon as possible and the second dose is taken 12 hours after the first.

Other possible side effects of IUD insertion include:

- heavy menstrual flow
- cramping
- infertility
- uterine puncture

Results

The effectiveness of emergency contraception depends both on the stage of the woman's menstrual cycle and on how soon the emergency contraception is used following unprotected vaginal intercourse. The closer a woman is to ovulation—her fertile period during which eggs are released from the ovary—the less effective emergency contraception will be.

ECPs are less effective than the most popular birth control methods:

- If taken within 72 hours of unprotected intercourse, combined ECPs are about 75% effective for preventing pregnancy.
- Progestin-only ECPs are 95% effective if taken within 24 hours of unprotected intercourse and about 89% effective if taken within 72 hours.

- A Copper-T IUD is 99.9% effective if inserted within seven days of unprotected intercourse.

If a normal menstrual period does not begin within three weeks after taking ECPs, or if signs of pregnancy develop, a healthcare provider should be consulted immediately.

Signs of pregnancy include:

- a missed menstrual period
- nausea
- unexplained fatigue
- enlarged or sore breasts
- headaches
- frequent urination

The majority of women express satisfaction with emergency contraception. One study of 235 women who had used ECPs found that 91% were satisfied with the method and 97% would recommend it to others.

Emerging diseases

Definition

Emerging diseases, also known as emerging infectious diseases or EIDs, are defined by the National Institute of Allergy and Infectious Diseases (NIAID) as "outbreaks of previously unknown diseases or known diseases whose incidence in humans has significantly increased in the past two decades." The institute also defines reemerging diseases as "known diseases that have reappeared after a significant decline in incidence."

Description

NIAID classifies emerging diseases into three groups.

WWW.BOOKBAZ.IR

Group I: disease organisms newly recognized since 1990

Group I is the largest category of emerging diseases and pathogens. It includes:

- Acanthamebiasis. This is an inflammation of the brain (encephalitis) caused by an ameba belonging to the genus *Acanthamoeba*. It is a relatively rare disease in humans but has a survival rate of only 3%.
- Australian bat lyssavirus (ABLV). Lyssavirus is a disease agent closely related to the rabies virus. ABLV was first identified in Australia in 1996. It can be transmitted to humans directly from bats without an intermediate host but can be prevented and treated in the same way as rabies infection. There have been three known deaths from ABLV as of 2014.
- Atypical babesiosis. Babesiosis is a disease caused by a parasitic protozoon that ordinarily causes only mild fever and diarrhea in humans but is potentially fatal in persons with weakened immune systems. The disease is carried to humans through the bite of ticks living in the fur of the white-footed mouse.
- *Bartonella henselae*. *B. henselae* is the disease agent of cat-scratch fever, which usually causes swelling of the lymph nodes as well as fever in humans.
- Ehrlichiosis. Ehrlichiosis is a disease characterized by headache, muscle aches, and fatigue. It is caused by bacteria of the genus *Ehrlichia*, which are carried by mouse and deer ticks.
- *Encephalitozoon cuniculi* and *Encephalitozoon hellem*. These are two species of parasitic protozoa that cause an intestinal infection known as microsporidiosis in persons with weakened immune systems. Microsporidiosis is characterized by severe diarrhea and tissue wasting.
- *Enterocytozoon bieneusi*. *E. bieneusi* is another parasitic protozoon that was first discovered in an AIDS patient in France in 1985. In 1996 it was found that pigs are the largest animal reservoir of the parasite.
- *Helicobacter pylori*. *H. pylori* is a curved rod-shaped bacterium that was first discovered in 1982 and identified as the cause of gastric ulcers in humans—a stomach disorder that was not previously thought to have a microbial cause.
- Hendra virus. Hendra virus, sometimes referred to as equine morbillivirus, was first identified in Australia in 1994 when it cause the death of 13 horses and their human trainer in Hendra, a suburb of Brisbane. Humans acquire the virus from close contact with horses. Four humans, including a veterinarian, died of Hendra virus in 2012.
- Hepatitis C and hepatitis E. These two forms of the hepatitis virus were discovered in 1989 and 1983 respectively. Hepatitis C exists only in humans and chimpanzees, while hepatitis E is commonly found in such animal reservoirs as pigs and deer.
- Human herpesvirus (HHV) 6 and HHV 8. Human herpesvirus 6 was first identified in 1986, with two subtypes, HHV-6A and HHV-6B. It is the cause of a childhood disease known as roseola infantum, characterized by fever and a reddish skin rash that lasts about two days. Human herpesvirus 8 is the virus associated with Kaposi's sarcoma, a skin cancer found in AIDS patients. HHV-8 was first identified in 1994.
- Lyme borreliosis. Lyme disease, also called Lyme borreliosis, was first diagnosed in Connecticut in 1978 although the disease agent, a bacterium belonging to the genus *Borrelia*, was not identified until 1981. Lyme disease is an emerging disease spread to humans by the bite of infected deer ticks.
- Parvovirus B19. Parvovirus B19 is a virus that causes a childhood disease called erythema infectiosum or slapped-cheek syndrome, so called because the affected person typically develops a bright red rash across the cheek area. It affects only humans. The virus may also cause chronic anemia in patients with AIDS.

Group II: reemerging disease organisms

Infectious diseases in this group include:

- Enterovirus 71. Enterovirus 71 is a virus that lives in the gut and is known to cause hand, foot and mouth disease (HFMD), a childhood infection characterized by fever, headache, and a red rash on the palms of the hands, soles of the feet, and the cheeks and area around the mouth. The virus is also capable, however, of causing severe and potentially fatal neurological disease in children.
- *Clostridium difficile*. *C. difficile* is a bacterium that lives in the human digestive tract; it can cause diarrhea and other intestinal disorders when the normal bacterial populations in the gut are wiped out by antibiotics..
- Mumps virus. Mumps virus infects only humans, where it causes a common childhood disease characterized by painful swelling of the salivary glands. It is vaccine-preventable, but has made a comeback in recent years due to opposition to compulsory vaccination on the part of some parents.
- Group A streptococci. Group A streptococci are a group of bacteria responsible for skin infections (erysipelas, impetigo), strep throat, septic arthritis, and

pneumonia. Acute rheumatic fever is a potential complication of a respiratory infection caused by these bacteria.

- *Staphylococcus aureus*. *S. aureus* is a common cause of skin infections, food poisoning, and sinusitis. It is an increasing problem in hospitals worldwide because it has developed resistance to penicillin, methicillin, and other antibiotics.

Group III: disease agents with bioterrorism potential

NIAID subdivides these pathogens into three priority categories:

- Priority category A: Category A pathogens are the highest priority because they are easily transmitted from person to person; have high mortality rates; are likely to cause public panic and widespread social disruption; and require special actions for public health preparedness. They include the agents that cause anthrax, botulism, plague, tularemia (rabbit fever), dengue, smallpox, hantavirus infections, and the viral hemorrhagic fevers.
- Priority category B: Category B pathogens have a lower mortality rate than those in category A and are only moderately easy to disseminate. They include the agents that cause Q fever, West Nile fever, brucellosis, typhus, psittacosis (parrot fever), cholera, food poisoning (*Salmonella* and *Shigella* species), listeriosis, hepatitis A, toxoplasmosis, giardiasis, LaCrosse encephalitis, and Japanese encephalitis.
- Priority category C: Category C disease agents have the potential to be weaponized in the future because of their availability, ease of distribution, and potential for high mortality rates. They include the pathogens that cause multidrug-resistant tuberculosis, yellow fever, influenza, rabies, prion diseases (Creutzfeldt-Jakob disease and mad cow disease), SARS, and such emerging diseases as Nipah fever, a disease caused by a virus in the same family as Hendra virus.

Origins

In the 1960s, many epidemiologists thought that infectious diseases were on their way to being permanently controlled because of such medical advances as the discovery of **antibiotics** and the widespread use of pesticides in underdeveloped countries, which kill the mosquitoes that spread **malaria** and other insect-borne diseases. The appearance of previously unknown contagious diseases, including Legionnaires' disease in 1976 and a hantavirus outbreak in Korea in 1978, combined with a resurgence of such diseases as **tuberculosis** and malaria, led to a reexamination of the persistence of infectious diseases.

The specific phrase *emerging diseases* first appeared in the medical literature in 1971, but does not appear to have been widely used until the early 1990s, when an article by an epidemiologist working with the World Health Organization (WHO) titled "Surveillance and Control of Emerging Zoonoses" was published in the *World Health Statistics Quarterly*. Emerging diseases was originally applied to infectious diseases previously unknown in humans; later the term was extended to include diseases that have been diagnosed in humans for many years but have only recently been identified as caused by an infectious agent.

The number of EIDs that affect humans has quadrupled since 1960, largely because of human behavior, changing demographics, and changes in land use. Humans come into increasingly frequent contact with new disease organisms or become increasingly susceptible to known pathogens in the following ways:

- Overuse of antibiotics. The addition of antibiotics to animal feed to increase meat production as well as the overprescribing of antibiotics to humans (particularly for viral diseases, against which antibiotics are ineffective) has led to the development of resistant pathogens, allowing many diseases that were formerly treatable with drugs to make a comeback. These diseases include malaria, tuberculosis, foodborne infections, and nosocomial (hospital-acquired) infections.
- Frequent and increasingly rapid international travel. The introduction of jet airplanes for commercial travel in the 1950s speeded up not only international trade but also the spread of communicable diseases. SARS and AIDS are two emerging diseases that were spread worldwide by aircrews as well as travelers.
- Increased susceptibility to infection among some humans due to compromised immune systems. In addition to persons with AIDS and other diseases that weaken the immune system, persons taking immunosuppressant drugs to prevent rejection of a transplanted organ and those receiving chemotherapy for cancer are also susceptible to opportunistic infections.
- Opposition to vaccination programs. In Western countries, concern about the safety of vaccines—particularly the measles/mumps/rubella or MMR vaccine—led many parents to refuse vaccination for their children. The MMR vaccine controversy resulted from a 1998 paper published by a British medical researcher named Andrew Wakefield, who

WWW.BOOKBAZ.IR

claimed that the vaccine caused autism and bowel disorders in some children. Although the paper was retracted in 2010 and Wakefield was subsequently charged with fraud, his 1998 article led to a sharp drop in the rate of vaccinations in the United Kingdom. There was a corresponding rise in the incidence of mumps and measles among British children, resulting in a number of deaths and permanent injuries.

- Changes in plant and animal habitats resulting from human interference with the natural environment—such as the widespread use of pesticides for disease control, deforestation in the tropics, and the expansion of human housing developments into previously intact temperate-zone forests. Lyme disease, for example, emerged as a human disease when the construction of new housing in central Connecticut chased away owls and other predators that kept the white-footed mouse population under control. When the mouse population multiplied fivefold, the infected deer ticks that live in the mouse's fur passed the bacteria that cause the disease to humans. Similarly, the Hendra virus emerged in Australia when infected fruit bats carrying the virus began to enter pastures and suburban back yards rather than remaining in the forests they previously inhabited. The movement of an EID from an animal reservoir to humans is known as spillover.
- Increased contact with exotic animals due to using them as food or keeping them as pets. The SARS virus is thought to have emerged into human communities in China, where the civet cats that carried the virus were used as meat. Similarly, there was an outbreak of monkeypox in the Midwestern United States in 2003 that was traced to an exotic animal dealer in Chicago who sold infected prairie dogs as pets.
- War and famine. People fleeing war zones or famine-stricken areas may carry emerging disease organisms with them to the countries where they seek refuge.
- Collapse of previously well-maintained systems of public health and hygiene. The recent political turmoil in Zimbabwe, for example, led to the closure of hospitals, the emigration of most healthcare professionals, a rapid increase in the number of cases of HIV infection, and several outbreaks of cholera. The cholera epidemic spread beyond Zimbabwe to Mozambique, Botswana, and Zambia. A new outbreak threatens.
- Bioterrorism. The 2001 anthrax attacks that followed 9/11 in the United States offered a preview of the potential of weaponized disease organisms to cause widespread panic in the general public. Although only five people died (17 others were infected), thousands of fearful people requested prescriptions for ciprofloxacin (an antibiotic used to treat anthrax) from their doctors.

Demographics

One reason for concern about EIDs is their high death toll. Infectious diseases are the leading cause of death worldwide, and the third highest cause of death in the United States. Most new emerging diseases—over 60%—are zoonoses; that is, they are transmitted to humans from animals. Of these zoonotic diseases, 70% originate in wildlife rather than domesticated animals or household pets.

An additional concern about EIDs is their capacity to interact with one another or with other diseases in ways that intensify the negative effects of each disease. The term syndemic has been coined to describe this type of disease combination. A syndemic differs from a comorbid condition in that it is possible for comorbid conditions to exist independently of each other even though the same patient has both disorders. An example of comorbidity would be a person who has both high blood pressure and arthritis. In a syndemic, by contrast, each illness worsens the virulence of the other. An example of a syndemic would be a patient who has both HIV and a herpesvirus infection; herpesvirus is known to speed the progression of HIV infection to full-blown **AIDS**. Syndemics associated with EIDs contribute significantly to the burden of disease worldwide.

Although some EIDs, such as Hendra virus, **SARS**, the hantaviruses, and acanthamebiasis are relatively uncommon the potential of others—particularly those caused by drug-resistant bacteria—to lead to epidemics or even pandemics affecting millions of people is of great concern to many epidemiologists. In addition, a bioterrorist attack involving any of the pathogens listed in NIAID's priority category A has the potential to lead to open warfare between nations that would add to the death toll caused by the disease itself.

Treatment

Efforts to identify new EIDs and develop preventive measures against them include the following:

- Establishment of specialized research centers, programs, and publications to improve the identification and surveillance of new EIDs, and obtain a clearer understanding of their methods of transmission. The CDC has created a specialized center for research into EIDs, the National Center for Emerging and Zoonotic Infectious Diseases (NCEZID). NCEZID has a subsection called the Emerging

KEY TERMS

Epidemic—An outbreak of a contagious disease that involves new cases of the disease in a specific human population during a given period substantially exceeding the number expected based on recent experience.

Incidence—The number of new cases of a specific disease within a specific time period within a specific population.

Opportunistic infection—An infection caused by pathogens that do not ordinarily cause disease in a healthy host but do produce disease in an immunocompromised person.

Pathogen—Any microorganism, virus, or other substance that causes disease in another organism.

Reservoir—In epidemiology, any species (including humans) that maintains a specific disease organism in nature.

Spillover—In epidemiology, the sporadic transmission of a disease agent from a reservoir species to a non-reservoir species.

Surveillance—In epidemiology, the monitoring and reporting of cases of contagious disease in order to establish patterns of its spread to prevent or minimize the development of epidemics and pandemics.

Syndemic—A combination of two or more diseases in a given population in which there is a positive biological interaction between the two diseases that intensifies their negative effects on health.

Virulence—The degree of a disease organism's ability to produce illness, as indicated by the mortality rate and/or the organism's ability to invade the host's tissues.

Zoonosis (plural, zoonoses)—Any disease that can be transmitted from animals to people or people to animals.

Infections Programs or EIP. The EIP is a network of ten state health departments linked to schools of public health and clinical laboratories in their respective states. In addition, the CDC publishes a monthly specialized journal titled *Emerging Infectious Diseases*. The U.S. Army maintains the Armed Forces Health Surveillance Center in Silver Spring, Maryland, which focuses on EIDs of concern to military personnel stationed abroad, particularly those deployed in countries with tropical climates. Other recently established centers of research into EIDs include those at the University of California, Berkeley, and The Pennsylvania State University.

- Development of new vaccines, therapies, and diagnostic tests to detect and treat EIDs promptly and effectively. There are at least 81 clinical trials registered with the National Institutes of Health to test the effectiveness of new vaccines, medications, and other treatments for EIDs ranging from hepatitis E and SARS to Group A streptococcal infections and West Nile virus.
- Setup and maintenance of international communication networks to monitor and report on EIDs. The International Society for Infectious Diseases (ISID) maintains a ProMED-mail system to facilitate international sharing of information and early warning about outbreaks of emerging and reemerging infectious diseases. ProMED stands for Program for Monitoring Emerging Diseases. The network currently links over 40,000 public health experts in 185 countries.
- Increasing cooperation among epidemiologists, veterinarians, and conservation biologists to better understand the emergence of new diseases from animal reservoirs, and the complexity of the interrelationships among humans, animals, geographic factors, and climate.

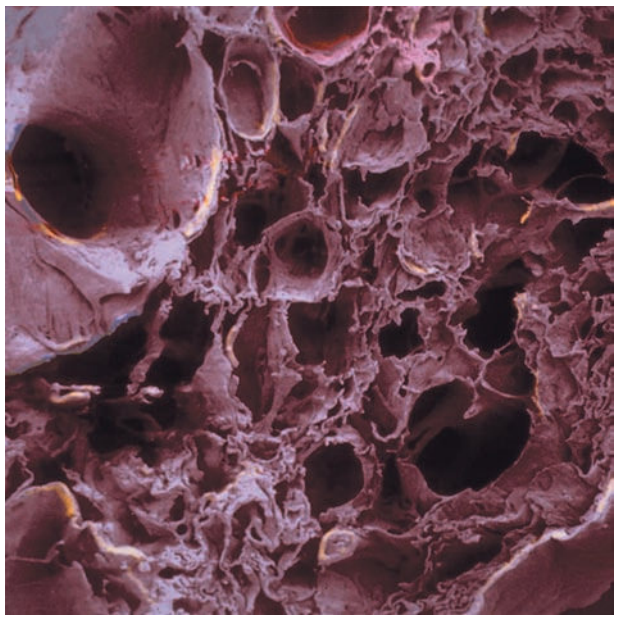
Emphysema

Definition

Emphysema is a chronic respiratory disease in which there is progressive overinflation of the air sacs (alveoli) in the lungs, causing a loss of lung function and often breathlessness. Its name comes from a Greek word meaning "to blow into," hence "air-containing" or "air-inflated." Emphysema is sometimes grouped together with chronic **bronchitis** under the name of **chronic obstructive pulmonary disease**, or COPD. Many people who are diagnosed with emphysema also have chronic bronchitis.

X ray showing emphysema in the lungs.
(Photo Researchers, Inc.)



A scanning electron microscopy (SEM) of lung tissue indicating emphysema. *(Custom Medical Stock Photo, Inc.)*

Demographics

Emphysema is increasing in the United States, Canada, and other developed countries primarily because of cigarette **smoking**. It is almost entirely a disease of adults. About 3.1 million adults in the United States have been diagnosed with the disease; however, many doctors believe emphysema is underdiagnosed. Between 4% and 6% of male adults and 1–3% of female adults in North America are estimated to have emphysema. The number of women diagnosed with the disease is rising rapidly; the year 2000 was the first year that more women than men were identified as having emphysema. In 2005, almost 66,000 females died compared to 61,000 males. According to the American Lung Association, the cost to the United States for COPD each year is approximately $42.6 billion, including $26.7 billion in direct health care expenditures, $8.0 billion in indirect morbidity costs and $7.9 billion in indirect mortality costs.

Rates of emphysema are rising worldwide as more people in the developing countries take up cigarette smoking. The Global Initiative for Chronic Obstructive Lung Disease (GOLD) estimates that 9–10% of adults around the world have either chronic bronchitis or emphysema.

People who develop emphysema as a result of smoking generally start to have symptoms in their late 40s or early 50s. Those who have emphysema because of a genetic condition may begin to have symptoms in their 30s. This genetic condition, discovered by a Swedish doctor in 1963 and known as alpha 1-antitrypsin deficiency (A1AT), is more common in Caucasians than in members of other races and accounts for about 2% of all emphysema cases in the United States. Current estimates suggest that between 60,000 and 100,000 Americans have severe A1AT deficiency, but only 4% of these patients have been identified.

Worldwide, people of Spanish, Portuguese, Scandinavian, and Saudi Arabian ancestry are at increased risk of emphysema associated with A1AT deficiency. The genetic disorder is thought to affect as many as 4% of these populations. Newborns in Sweden are routinely screened for A1AT deficiency.

Description

Emphysema is a lung disease in which a person's ability to breathe easily and deeply is steadily weakened over time by the destruction of lung tissue. The human lung consists of tissue containing millions of tiny air sacs called alveoli, which are arranged like bunches of grapes around very small air tubes called bronchioles. There are about 300 million alveoli in each lung. When a person breathes in air, the air travels from the nose and mouth through the windpipe and then into the right and left bronchi, which are the main air passages into each of the two lungs. The bronchi divide and subdivide repeatedly into smaller and smaller air passages, finally ending in the bronchioles and alveoli. In a normal person, oxygen from the air that has been taken in is exchanged in the walls of the alveoli for carbon dioxide in the person's blood. When the person breathes out, the carbon dioxide leaves the body in the air that travels out from the lungs and through the upper airway to the nose and mouth.

To perform their function effectively, the tissue in the lungs that separates the alveoli from one another needs to be as elastic as possible. The alveoli contain tiny elastic fibers in their cell walls that allow them to act like miniature balloons. What happens in emphysema is that tobacco smoke or other irritants causes the alveoli to become inflamed and lose their elasticity. The bronchioles start to collapse, which traps air inside the alveoli and overstretches them. In time the alveoli rupture, leading to the formation of fewer but larger air sacs in the lungs. The smaller areas of alveoli destruction are known as blebs and the larger ones are called bullae. These larger and less flexible sacs are less efficient in forcing air out of the lungs when the person

WWW.BOOKBAZ.IR

breathes out. As a result, the person has to breathe more frequently or breathe harder in order to get enough oxygen and get rid of carbon dioxide.

In addition to the loss of elasticity in the alveoli, the cells in the airways secrete more mucus than usual, which collects in the airways and clogs them, making breathing even more difficult.

Risk factors

Cigarette smoking is the biggest single risk factor for emphysema. Some people who do not smoke cigarettes, however, are at increased risk of emphysema. They include:

- People who work in occupations that expose them to high levels of dust from grain or cotton, or chemical irritants. These occupations include mining, certain types of agricultural work, and lumbering. Most miners suffer from emphysema to some degree after a lifetime in the mining pit. In fact, emphysema is sometimes referred to as miner's lung or black lung.
- People exposed to high levels of automobile exhaust or secondhand smoke.
- People who are HIV-positive.
- People who abuse intravenous drugs. The cotton fibers and other materials used as fillers in these drugs can irritate and eventually destroy lung tissue.
- People who smoke marijuana. Marijuana smoke may be even more damaging to some people than tobacco because it is inhaled deeply and held in by the smoker.
- People with certain diseases that affect connective tissue, such as Marfan syndrome and Ehlers-Danlos syndrome.
- People whose occupations require heavy use of the lungs for blowing, such as trumpet players, woodwind players, and glassblowers.

Causes and symptoms

Causes

Emphysema is caused by a weakening of the tissues in the lungs as a result of inflammation due to tobacco smoke or other chemical irritants in the air, or a hereditary deficiency of a protein that protects the elasticity of lung tissue. As the bronchioles in the lungs collapse and the alveoli become enlarged, the lungs become less efficient in getting rid of carbon dioxide and the person has to breathe more frequently in order to get enough oxygen. In addition, the person has to use their chest muscles to expel air from the lungs forcefully rather than being able to rely on the normal movement of the diaphragm during breathing. This need to use muscular force leads to the development of a so-called barrel chest; that is, the person's chest is almost the same size from front to back as from side to side.

About 2% of cases of emphysema are caused by a deficiency of a liver enzyme known as alpha 1-antitrypsin, or A1AT. The enzyme ordinarily protects the alveoli in the lungs from damage by another enzyme that harms connective tissue. In people with A1AT deficiency, there is not enough of the protective enzyme to keep the alveoli in good working condition. A1AT is an inherited condition caused by a mutation in a gene on the long arm of chromosome 14.

Symptoms

The most noticeable symptoms of emphysema are breathlessness, coughing, and **wheezing**. These symptoms typically develop gradually over many years. It is a common occurrence for many emphysema patients to have lost over half of their functioning lung tissue before they become aware that something is wrong. The **cough**, which is often dismissed as "smoker's cough," may be productive of large amounts of dark, thick sputum.

In addition to **shortness of breath**, coughing, and wheezing, people with emphysema often develop the following symptoms:

- Pursed-lips breathing. This is a way of partially closing the lips that allows the person to fully exhale. When the mouth opening is smaller, the airways that have been weakened by the disease open wide and allow the person to expel more air from the lungs.
- Greater difficulty exercising or doing work that requires physical activity.
- Loss of appetite and weight loss. Eating can make it harder to breathe because the stomach expands during a meal and pushes upward against the diaphragm.
- Fatigue. Emphysema leads to a lower level of oxygen in the blood, which in turn causes people to feel tired easily.
- Swelling of the feet, ankles, or legs.
- Slow recovery from such upper respiratory infections as colds and flu. Those with emphysema are at risk for a variety of other complications resulting from weakened lung function, including pneumonia, pulmonary hypertension, cor pulmonale, and chronic respiratory failure.

KEY TERMS

Alveolus (plural: alveoli)—The medical term for one of the tiny air sacs in the lungs where oxygen is transferred from the lungs to the blood and carbon dioxide is removed.

Arterial blood gases test—A test to analyze blood for oxygen, carbon dioxide, and bicarbonate content, as well as blood pH (acidity level). Used to test the effectiveness of respiration.

Bronchiole—A very small thin-walled air passage in the lungs that branches off from a bronchus.

Bronchus (plural: bronchi)—One of the two major divisions of the airway that lead into the right and left lungs.

Cor pulmonale—Enlargement and structural change of the right ventricle of the heart as a result of emphysema or other respiratory disorder.

Diaphragm—A sheet of muscle tissue that divides the chest cavity from the abdominal cavity.

Peak flow measurement—Measurement of the maximum rate of airflow attained during a forced vital capacity determination.

Progressive—A term that refers to a disease that gets worse over time.

Pulmonary—Related to or associated with the lungs.

Pulse oximetry—The noninvasive monitoring or determination of oxygen-hemoglobin saturation of the blood.

Spirometer—A device that is used to test the air capacity of a person's lungs and the amount of air that enters and leaves the lungs during breathing.

Ventricle—One of the two lower chambers of the heart.

Diagnosis

Many patients are diagnosed with emphysema in the course of seeking treatment for chronic bronchitis. The first step in diagnosing emphysema is a careful patient history, particularly a history of smoking.

Examination

A history of heavy smoking alone, however, is not enough for a physician to differentiate emphysema from other respiratory diseases. A physician will combine information on symptoms, medical history, **physical examination**, lung function tests, and chest x ray results to make a diagnosis of emphysema. One of the first clues may be a hollow sound heard through a stethoscope as the patient's chest is being tapped. The hollow sound is the result of the enlargement or rupture of the lungs' alveoli.

Tests

A variety of **pulmonary function tests** may be ordered. In the early stages of emphysema, the only result may be dysfunction of the small airways. Patients with emphysema may show an increase in the total amount of air that is in the lungs (total lung capacity), but a decrease in the amount of air that can be breathed out after taking a deep breath (vital capacity). With severe emphysema, vital capacity is substantially below normal. **Spirometry**, a procedure that measures air flow and lung volume, helps in the diagnosis of emphysema.

A chest x ray is often ordered to aid in the diagnosis of emphysema, though patients in the early stages of the disease may have normal findings. Abnormal findings on the chest x ray include overinflation of the lungs and an abnormally increased chest diameter. The diaphragm may appear depressed or flattened. In addition, patients with advanced emphysema may show a smaller or vertical heart. The physician may observe blisters in the lungs and bulging of the accessory muscles of the respiratory system. Late in the disease, an EKG will show signs of right ventricular failure in the heart and increased hemoglobin due to lower levels of oxygen in the patient's blood.

Other tests that may be performed include peak flow measurements, arterial blood gases, and pulse oximetry.

A1AT deficiency can be diagnosed by a simple fingerstick blood test. Individuals with symptoms of emphysema or COPD should ask their doctor whether this test is appropriate for them. Their doctor can order the test, or they can choose to be tested on a confidential basis through the Alpha-1 Foundation's Alpha-1 Coded Testing (ACT) study.

Treatment

There is no cure for emphysema as of 2014. Treatment is focused on slowing the progress of the disease and easing the patient's symptoms. The first part of treatment for patients who smoke is quitting the habit. Smoking cessation programs may be effective. Consistent encouragement along with the help of health care professionals as well as family and friends can

WWW.BOOKBAZ.IR

help increase the success rate of someone attempting to quit smoking.

Traditional

DRUGS. The next stage in treatment is the use of medications. The doctor may prescribe one or more of the following types of drugs:

- Bronchodilators. Bronchodilators are drugs that work by opening up the airways, which allows for more efficient exchange of carbon dioxide and oxygen. Some are taken in tablet form while others are dispensed in inhalers. Depending on the severity of the patient's emphysema, they may use the inhaler only when needed for shortness of breath or they may take a dose of the medication at prescribed regular intervals. There are three primary categories of bronchodilators: sympathomimetics (isoproterenol, metaproterenol, terbutaline, albuterol), which can be inhaled, taken by mouth, or injected; parasympathomimetics (atropine); and methylxanthines (theophylline), which may be administered intravenously, orally, or rectally.
- Steroids (beclomethasone, dexamethasone, triamcinolone, flunisolide). This type of medication works by lowering the inflammation in the tissues lining the airways. These drugs can also be taken in pill form or through inhalers. Some patients' lung function improves with corticosteroids, and inhaled steroids may be beneficial to patients with few side effects.
- Antibiotics. People who have infections in the lungs as well as emphysema may be given antibiotics to treat the infections.
- Expectorants. These are drugs that can help to loosen respiratory secretions, enabling the patient to more easily expel them from the airways.

Many of the medications prescribed for emphysema involve the use of a metered dose inhaler (MDI) that may require special instruction to be used correctly. MDIs are a convenient and safe method of delivering medication to the lungs. If they are used incorrectly, however, the medication will not get to the right place. Proper technique is essential for inhaled medication to be effective.

Among all other treatments for emphysema, only **oxygen therapy** has shown an increase in the survival rate.

Home oxygen therapy may improve the survival times in those patients with advanced emphysema who also have low blood oxygen levels. It may improve the patient's tolerance of **exercise**, as well as improve their performance in certain aspects of brain function and muscle coordination. The functioning of the heart may also improve with an increased concentration of oxygen in the blood. Oxygen may also decrease **insomnia** and headaches. Some patients may receive oxygen only at night, but studies have illustrated that it is most effective when administered at least 18 but preferably 24 hours per day. Portable oxygen tanks prescribed to patients carry a limited supply and must be refilled on a regular basis by a home health provider. Medicare and most insurance companies cover a large proportion of the cost of home oxygen therapy. Patients should be instructed regarding special safety issues involving the transport and presence of oxygen in the home.

Surgery

Emphysema is sometimes treated surgically. In some cases, part of the diseased lung is removed. This procedure, which is called lung volume reduction, creates space for the remaining portions of the lungs; it does improve breathing and quality of life for some patients. Another surgical option is **lung transplantation**. This is a risky procedure and requires the patient to take medications to prevent the rejection of the transplanted lung. In addition, not everyone qualifies for transplantation, and those who do are limited by the short supply of available organs. Up through 2006, emphysema was the single most common diagnosis of American patients awaiting lung transplantation.

Other interventions

For those patients with advanced emphysema, keeping the air passages reasonably clear of secretions can prove difficult. Some common methods for mobilizing and removing secretions include:

- Postural drainage. This helps to remove secretions from the airways. The patient lies in a position that allows gravity to aid in draining different parts of the lung. This is often done after the patient inhales an aerosol medication. The basic position involves the patient lying on the bed with his chest and head over the side and the forearms resting on the floor.
- Chest percussion. This technique involves lightly clapping the back and chest, and may help to loosen thick secretions.
- Coughing and deep breathing. These techniques may aid the patient in bringing up secretions.
- Aerosol treatments. These treatments may involve solutions of saline, often mixed with a bronchodilator, which are then inhaled as an aerosol. The aerosols thin and loosen secretions. A treatment normally takes 10–15 minutes, and is given three or four times a day.

Another important part of treatment for emphysema is called pulmonary **rehabilitation**. This approach is aimed at educating patients about their disease and helping them with lifestyle changes that will slow the progression of the disease and improve quality of life. Pulmonary rehabilitation includes a physical exercise program designed to improve the patient's physical endurance and energy level. Many patients are also encouraged to lose weight in order to reduce the burden on their lungs. One important benefit of pulmonary rehabilitation is psychological: patients report that their self-esteem and sense of control over their life improve when they start to see benefits from the rehabilitation program.

Patients with emphysema can learn to perform a variety of self-help measures that may help improve their symptoms and their ability to participate in everyday activities. These measures include:

- Avoiding any exposure to dust and fumes.
- Avoiding air pollution, including secondhand cigarette smoke.
- Avoiding other people who have infections like colds or flu, and getting a pneumonia vaccination and a yearly flu shot.
- Drinking plenty of fluids. This helps to loosen respiratory secretions so they can be brought up more easily through coughing.
- Avoiding extreme temperatures of heat or cold, and also avoiding high altitudes. Special precautions can be taken that may enable the emphysema patient to fly on a plane.
- Maintaining adequate nutritional intake. Normally a high-protein diet taken in many small feedings is recommended.

Treatment for A1AT deficiency

Emphysema related to A1AT deficiency can be treated by intravenous infusions of the A1AT protein as well as by avoiding breathing substances that irritate the lungs and by lung transplantation if needed. The intravenous protein infusions are derived from donated human blood plasma. This type of treatment is called augmentation therapy; present recommendations are that patients should not begin this treatment before the symptoms of emphysema appear. Augmentation therapy is not a cure for emphysema but can slow its progression.

Alternatives

There are several alternative approaches to relieving the symptoms of emphysema. As with mainstream treatments, these are not cures for the disease.

HERBALISM. Herbs can be beneficial in helping the body to ward off infection, and easing the asthmatic symptoms that often accompany emphysema.

Some beneficial herbs are:

- Lobelia. This is a mild sedative, also having strong expectorant properties. It is widely used for chest complaints, including emphysema and bronchitis, and can help to shorten an asthma attack.
- Thyme. A tea made with thyme is recommended for overcoming shortness of breath. It is also a powerful antiseptic.
- Mullein. This is another traditional remedy for chest complaints. To make a tea, one boils two tablespoons of the dried leaves with a glass of milk and drinks the mixture.
- Echinacea. Echinacea is a powerful immune system stimulant and strengthens the body in general, warding off colds and infections.
- Lungwort. A member of the borage family, this herb is very healing for the lungs. It should be taken as an infusion.
- Black cohosh. This herb is an expectorant and astringent. It relieves coughing.
- Sage. This is one of the most useful of all herbs and is said to be good for whatever it is taken for. It is antiviral and bactericidal.
- Garlic. A very powerful antiviral, garlic can be of real help to those trying to avoid infections and lung congestion.

CHINESE HERBAL MEDICINE. Qing Qi Hua Tan Wan (Pinellia expectorant pills) are the Chinese herbalists' treatment for chronic lung complaints, particularly bronchitis and **asthma**.

JUICE THERAPY. Kitty Campion, a British naturopathic herbalist expert, recommends the following juices for the treatment of emphysema: equal parts of carrot juice, parsnip juice, watercress juice, and potato juice, or equal parts of orange juice and lemon juice, diluted half and half with a strong decoction of rosehip tea.

AROMATHERAPY. **Aromatherapy** involves massaging the patient with potent plant essential oils, which have been proven to enter the circulation through the skin. The constituents of the oils can have a powerful effect on a variety of illnesses, but since their beneficial qualities are also transported through the air, they are considered to be doubly beneficial to those who have respiratory ailments.

WWW.BOOKBAZ.IR

Aromatherapy oils for respiratory disease:

- *Canada balsam* may alleviate respiratory symptoms and is an expectorant. It is also a bactericide and recommended for those suffering from chronic chest ailments.
- *Tolu balsam* is an excellent treatment for chest infections.
- *Frankincense* is good for infection and catarrhal discharge.
- *Niaouli* is a very strong antiseptic and beneficial for pulmonary trouble.
- *Rose damascena* is recommended for bronchial complaints, and it also lifts the spirits.
- *Tea tree oil* is one of the most potent anti-viral, anti-bacterial and anti-fungal agents known to herbal medicine, therefore, highly beneficial as a preventative measure against chest infection.

ACUPUNCTURE. This ancient Chinese system of holistic treatment works on the principle that illness is the result of blockage in the flow of life force. The practitioner aims to stimulate relevant meridians in the body and thus release trapped life force, returning bodily functions to normal. The treatment is virtually painless.

Treatment can be expected to improve blood circulation and the capacity of the body to restore itself. Research has indicated that **acupuncture** can produce changes in the electrical fields of body cells, which promote a return to the body's normal state. Consequently, few negative side effects are associated with acupuncture treatment.

Prognosis

Emphysema is known to shorten a patient's life span. It is the fourth most common cause of death in the United States, being responsible for 4.5% of all deaths and a contributing factor in another 4.3%. Some patients, however, live longer than others depending on the cause of their emphysema and the measurement of their lung capacity at diagnosis. Complications of emphysema include higher risks for **pneumonia** and acute bronchitis. In general, men have worse prognoses than women. Patients who have smoked 20 cigarettes per day for 20 years or longer with a severely reduced breathing capacity have the worst prognosis; only 5% survive for 12 years after diagnosis. Smoking has been estimated to speed up the appearance of emphysema in patients with A1AT deficiency by 19 years.

The prognosis for emphysema associated with A1AT deficiency is poor. Long-term studies of the efficacy of augmentation therapy have not been carried although the therapy has been used for about 20 years and is considered safe. Most patients with this form of emphysema have some degree of disability and a shortened life expectancy.

Prevention

Most cases of emphysema can be prevented by simply not smoking or by quitting smoking as soon as possible and avoiding secondhand smoke. Emphysema related to genetic factors cannot always be prevented, but its development can be postponed in people who inherited the defective gene by avoiding smoking.

Empyema

Definition

Empyema is a condition in which pus and fluid from infected tissue collects in a body cavity. The name comes from the Greek word *empyein* meaning pus-producing (suppurate). Empyema is most often used to refer to collections of pus in the space around the lungs (pleural cavity), but sometimes refers to similar collections in the gall bladder or the pelvic cavity. Empyema in the pleural cavity is sometimes called empyema thoracis, or empyema of the chest, to distinguish it from empyema elsewhere in the body.

Description

Empyema may have a number of causes but is most frequently a complication of **pneumonia**. Its development can be divided into three phases: an acute phase in which the body cavity fills with a thin fluid containing some pus; a second stage in which the fluid thickens and a fibrous, coagulation protein (fibrin) begins to accumulate within the cavity; and a third or chronic stage in which the lung or other organ is encased within a thick covering of fibrous material.

Causes and symptoms

Empyema thoracis can be caused by a number of different organisms, including bacteria, fungi, and amebas, in connection with pneumonia, chest **wounds**, chest surgery, lung abscesses, or a ruptured esophagus. The infective organism can get into the pleural cavity either through the bloodstream or other circulatory system, in secretions from lung tissue, or on the surfaces of surgical instruments or objects that cause open chest wounds. The most common organisms that cause empyema are the following bacteria: *Streptococcus pneumoniae*, *Haemophilus influenzae*, and *Staphylococcus aureus*. *S. aureus* is the most common cause in all age groups, accounting for 90% of cases of empyema in infants and children. Pelvic empyema in women is most often caused by *Bacteroides* strains or *Pseudomonas aeruginosa*. In elderly, chronically ill, or alcoholic patients, empyema is often caused by *Klebsiella pneumoniae* species of bacteria.

When the disease organisms arrive in the cavity surrounding the lungs, they infect the tissues that cover the lungs and line the chest wall. As the body attempts to fight off the infection, the cavity fills up with tissue fluid, pus, and dead tissue cells. Empyema of the gall bladder or pelvis results from similar reactions to infection in those parts of the body.

The signs and symptoms of empyema vary somewhat according to the location of the infection and its severity. In empyema thoracis, patients usually exhibit symptoms of pneumonia, including **fever**, **cough**, **fatigue**, **shortness of breath**, and chest **pain**. They may prefer to lie on the side of the body affected by the empyema. Family members may notice **bad breath**. In severe cases, the patient may become dehydrated, cough up blood or greenish-brown sputum, run a fever as high as 105°F (40.6°C), or fall into a **coma**.

WWW.BOOKBAZ.IR

Patients with thoracic empyema may develop potentially life-threatening complications if the condition is not treated. The infected tissues may develop large collections of pus (abscesses) that can rupture into the patient's airway, or the infection may spread to the tissues surrounding the heart. In extreme cases the empyema may spread to the brain by means of bacteria carried in the bloodstream.

In pelvic empyema, the infection produces large amounts of thick, foul-smelling pus that is rapidly replaced even after drainage. Empyema of the gallbladder is marked by intense pain on the upper right side of the abdomen, high fever, and rigidity of the muscles over the infected area.

Diagnosis

A physician may consider the possibility of empyema thoracis in patients with pneumonia or other symptoms of lung infection. When listening to sounds within the patient's chest with a stethoscope, the sounds of breathing will be partly muffled and harder to hear in the patients with empyema. The area of the chest over the infection will sound dull when tapped or thumped (percussed). On an x ray, empyema thoracis will appear as a cloudy or opaque area. The amount of fluid present in the pleural cavity can be estimated using an **ultrasound** imaging procedure. The diagnosis of empyema, however, has to be confirmed with laboratory tests because its symptoms can be caused by other disease conditions.

The diagnosis of empyema is usually confirmed by analyzing a sample of fluid taken from the pleural cavity. The sample is obtained by a procedure called **thoracentesis**. In this procedure, the patient is given a local anesthetic, a needle is inserted into the pleural cavity through the back between the ribs on the infected side, and a sample of fluid is withdrawn. If the patient has empyema, there will be a very high level of one particular kind of immune cell (white blood cells), a high level of protein, and a very low level of blood sugar. The fluid can also be tested for the specific disease organism by staining or tissue cultures. In some cases, the color, smell, or consistency of the tissue fluid also helps to confirm the diagnosis.

Treatment

Empyema is treated using a combination of medications and surgical techniques. Treatment with medication involves intravenously administering a two-week course of **antibiotics**. It is important to give antibiotics as soon as possible to prevent first-stage empyema from progressing to its later stages. The antibiotics most commonly used are penicillin and vancomycin. Patients experiencing difficulty breathing are also given **oxygen therapy**.

Surgical treatment of empyema has two goals: drainage of the infected fluid and closing up of the space left in the pleural cavity. If the infection is still in its early stages, the fluid can be drained by thoracentesis. In second-stage empyema, the surgeon will insert a chest tube in the patient's rib cage or remove part of a rib (rib resection) in order to drain the fluid. In third-stage empyema, the surgeon may cut or peel away the thick fibrous layer coating the lung. This procedure is called decortication. When the fibrous covering is removed, the lung will expand to fill the space in the chest cavity. The doctor can use **video-assisted thoracic surgery** (VATS) techniques to position the chest tube or to perform a limited decortication. The VATS

KEY TERMS

Abscess—An area of inflamed and injured body tissue that fills with pus.

Decortication—Surgical removal of the fibrous peel that covers the lungs in third-stage empyema.

Empyema—The collection of pus in a body cavity, particularly the lung or pleural cavity.

Fibrin—A fibrous blood protein vital to coagulation and blood clot formation.

Percussion—A diagnostic technique in which the back, chest, or abdomen is tapped to determine whether body cavities contain abnormal fluid.

Pleural cavity—The space surrounding the lungs, including the membranes covering the lungs and lining the inside of the chest wall.

Pneumonia—Inflammation of the lungs usually caused by a virus, bacteria, or other organism.

Resection—The surgical removal of part of an organ or body structure, as in rib resection.

Suppurate—To produce or discharge pus.

Thoracentesis—A procedure in which fluid is withdrawn from the pleural cavity through a needle inserted between the ribs. The fluid may be withdrawn either for diagnostic tests or to drain the cavity.

Video-assisted thoracic surgery (VATS)—A technique used to aid in the placement of chest tubes or when performing decortications when treating advanced empyema.

technique allows a physician to see within the body during certain surgical procedures. Empyema of the gallbladder is a serious condition that is treated with intravenous antibiotics and surgical removal of the gallbladder.

Prognosis

The prognosis for recovery is generally good, except in those cases with complications, such as a **brain abscess** or blood **poisoning**, or cases caused by certain types of streptococci.

Encephalitis

Definition

Encephalitis is an inflammation of the brain, usually caused by a direct viral infection or a hypersensitivity reaction to a virus or foreign protein. Brain inflammation caused by a bacterial infection is sometimes called cerebritis. When both the brain and spinal cord are involved, the disorder is called encephalomyelitis. An inflammation of the brain's covering, or meninges, is called meningitis.

Description

Encephalitis is an inflammation of the brain. The inflammation is a reaction of the body's immune system to infection or invasion. During the inflammation, the brain's tissues become swollen. The combination of the infection and the immune reaction to it can cause headache and a fever, and in some cases, more severe symptoms can result.

There are several types of encephalitis. They include California encephalitis, which occurs throughout the western United States; St. Louis encephalitis, which occurs throughout the U. S., and Japanese encephalitis, which is found throughout much of Asia. Another type of encephalitis is equine encephalitis. This is a disease carried by mosquitoes that normally horses and birds. It is occasionally picked up from these animals by mosquitoes that do bite humans, however, and can cause illness in people. Equine encephalitis has both a western and eastern form. Eastern equine encephalitis occurs in eastern and southeastern United States; and western equine is found throughout the western United States. These are only a few of the types of encephalitis.

Another form of encephalitis is herpes simplex encephalitis, which is responsible for 10% of all encephalitis cases and is the main cause of sporadic, fatal encephalitis. In untreated patients, the rate of death from herpes simplex encephalitis is 70%.

When encephalitis spreads directly to the brain, it is termed primary encephalitis. The viruses causing primary encephalitis can be epidemic (occurring in an unusual frequency) or sporadic (occurring singly or in small clusters of cases). Arthropod-borne viral encephalitis is responsible for most epidemic viral encephalitis. The viruses live in animal hosts and mosquitos that transmit the disease. The most common form of non-epidemic or sporadic encephalitis is caused by the herpes simplex virus, type 1 (HSV-1) and has a high rate of death. Mumps is another example of a sporadic cause.

Demographics

The incidence of acute encephalitis is estimated at 7.4 per 100,000 persons in Western countries, and 6.34 per 100,000 people in tropical countries. The number of deaths worldwide due to this disease is decreasing: Globally, it caused an estimated 144,000 deaths in 1990, and an estimated 120,000 in 2010.

Causes and symptoms

Causes

More than a dozen viruses can cause encephalitis. Primary encephalitis results from direct infection by the virus, while secondary encephalitis results from a post-infectious immune reaction to viral infection elsewhere in the body. Encephalitis-causing viruses may be spread by human-to human contact or via animal bites. Viruses and viral diseases that may cause encephalitis include:

- Chickenpox, measles, mumps, rubella, and Epstein-Barr virus (EBV), which are often associated with secondary encephalitis.
- Cytomegalovirus, which is a genus of viruses related to those that cause chickenpox and infectious mononucleosis

WWW.BOOKBAZ.IR

- Herpes simplex. Herpes simplex encephalitis, the most common form of sporadic encephalitis in western countries, is a disease with significantly high mortality. It occurs in children and adults and both sides of the brain are affected. It is theorized that brain infection is caused by the virus moving from a peripheral location to the brain via two nerves, the olfactory and the trigeminal (largest nerves in the skull).
- Rabies, which is most often spread by animal bites from dogs, cats, mice, raccoons, squirrels, and bats.
- Mosquito-borne viruses (known collectively as arbovirus encephalitis). Mosquitoes spread viruses responsible for several types of encephalitis, including equine encephalitis (eastern and western types), St. Louis encephalitis, California encephalitis, and Japanese encephalitis. The risk of contracting a mosquito-borne virus is greatest in mid- to late summer, when mosquitoes are most active, in those rural areas where these viruses are known to exist.

In rare cases, encephalitis may follow vaccination against some of these viral diseases. Other causes of encephalitis include Creutzfeldt-Jakob disease, a very rare brain disorder caused by an infectious particle called a prion; Colorado tick fever and Lyme disease, which are transmitted by the Rocky Mountain wood tick (*Dermacentor andersoni*) and deer tick (*Ixodes scapularis*), respectively; and the viruses associated with HIV, herpes zoster (shingles), herpes B, and polio.

Symptoms

The symptoms of encephalitis range from very mild to very severe and may include:

- headache
- fever
- lethargy (sleepiness, decreased alertness, and fatigue)
- malaise
- nausea and vomiting
- visual disturbances
- tremor
- decreased consciousness (drowsiness, confusion, delirium, and unconsciousness)
- stiff neck
- seizures

Symptoms may progress rapidly, changing from mild to severe within several days or even several hours.

In secondary encephalitis, symptoms usually begin 5–10 days after the onset of the disease itself and are related to the breakdown of the insulating myelin sheath that covers nerve fibers.

Diagnosis

Diagnosis of encephalitis includes careful questioning by the doctor to determine possible exposure to viral or bacterial sources. Tests that can help confirm the diagnosis and rule out other disorders include:

- Blood tests, which are used to detect antibodies to viral antigens (a virus that provokes an immune response) and foreign proteins.
- Cerebrospinal fluid analysis (spinal tap), which is used to detect viral antigens, and to provide culture specimens for the virus or bacteria that may be present in the cerebrospinal fluid.
- Electroencephalogram (EEG).
- CT and MRI scans.

A brain biopsy (surgical removal of a small tissue sample) may be recommended in some cases where treatment to date has been ineffective and the cause of the encephalitis is unclear. Definitive diagnosis by biopsy may allow specific treatment that would otherwise be deemed too risky.

Treatment

The choice of treatment for encephalitis depends on the cause. Bacterial encephalitis is treated with antibiotics. Viral encephalitis is usually treated with antiviral drugs including acyclovir, ganciclovir, foscarnet, ribovarin, and azidothymidine (AZT). Viruses that respond to acyclovir include herpes simplex, the most common cause of sporadic encephalitis in the United States.

The symptoms of encephalitis may be treated with a number of different drugs. Corticosteroids, including prednisone and dexamethasone, are sometimes prescribed to reduce inflammation and brain swelling. A randomized control study trial of the effectiveness of corticosteroids in encephalitis due to herpes simplex virus was scheduled to begin in 2014. Anticonvulsant drugs, including dilantin and phenytoin, may be used to control seizures. Fever may be reduced with acetaminophen or other fever-reducing drugs.

A person with encephalitis must be monitored carefully, since symptoms may change rapidly. Blood tests may be required regularly to track levels of fluids and salts in the blood.

KEY TERMS

Cerebrospinal fluid analysis—An analysis of fluid that surrounds and protects the spinal cord and brain to indicate the presence of viruses, bacteria, and blood.

Computerized tomography (CT) scan—A test to examine organs within the body and detect evidence of tumors, blood clots, and accumulation of fluids.

Electroencephalagram (EEG)—A chart of the brain waves picked up by the electrodes placed on the scalp. Changes in brain wave activity can be an indication of nervous system disorders.

Inflammation—A immune-system response, which may include redness, heat, swelling, and pain, to an injury.

Magnetic resonance imaging (MRI)—MRI is diagnostic radiography using electromagnetic energy to create an image of the central nervous system, blood system, and musculoskeletal system.

Vaccine—A preparation containing killed or weakened microorganisms used to build immunity against infection from that microorganism.

Prognosis

Most cases of encephalitis are mild with symptoms that may last several weeks, and recovery is usually quick. Mild encephalitis usually leaves no residual neurological problems, although permanent neurological consequences may follow recovery in some cases. Consequences may include personality changes, memory loss, language difficulties, seizures, and partial paralysis. Overall, approximately 10% of those with encephalitis die from their infections or from complications such as secondary infection.

Some forms of encephalitis have more severe courses. These include herpes encephalitis, in which mortality is 70–80% without treatment. Equine encephalitis also carries high danger, with a mortality rate of about 33%, and survivors typically experiencing significant brain damage.

Prevention

In some cases, encephalitis may be prevented by avoiding the infection that causes it. Most infections are spread by hand-to-hand or hand-to-mouth contact, so frequent hand washing may reduce the likelihood of infection if contact cannot be avoided. In addition, minimizing contact with others who have infectious, encephalitis-associated viral illnesses may reduce the chances of becoming infected.

Mosquito-borne viruses may be avoided by taking preventive measures against bites from these insects. Mosquitoes are most active at dawn and dusk in moist areas with standing water, so avoiding these areas, minimizing exposed skin, and using mosquito repellents can reduce the chances of being bitten.

Vaccines are available against some viruses, including polio, herpes B, Japanese encephalitis, and equine encephalitis. Rabies vaccine is available for animals, and is also given to people after exposure. Japanese encephalitis vaccine is recommended for those traveling to Asia and visiting affected rural areas during transmission season.

Encephalopathy

Definition

Encephalopathy is a condition characterized by altered brain function and structure. It is caused by diffuse brain disease.

Description

Encephalopathy may be caused by advanced and severe disease states, infections, or as a result of taking certain medications. The three main causes of encephalopathy are **liver disease**, **kidney disease**, and lack of oxygen in the brain. The associated symptoms can include subtle personality changes, inability to concentrate, lethargy, progressive loss of memory and thinking abilities, progressive loss of consciousness, and abnormal involuntary movements. Symptoms vary with the severity and type of encephalopathy.

Cerebral **edema** is a common manifestation of severe encephalopathy, which causes an increase in intracranial pressure. The major related causes of death include **sepsis**, circulatory collapse, and brain failure related to a syndrome encompassing cerebral edema, damaged blood-brain-barrier, increased intracranial pressure, brainstem herniation, and/or neurotoxins leaking into the brain and killing brain cells. Additionally, patients with severe encephalopathy usually develop intracranial **hypertension**, which can produce cerebral ischemia injury and cerebral herniation.

Demographics

There is no statistical information available for encephalopathy per se. It can occur at any age, and, because it is a manifestation of another primary illness, there seems to be no gender or racial predilections for the disorder.

Causes and symptoms

Causes

There is a wide variety of conditions that cause encephalopathy. It can be caused by infections (bacteria, viruses, or prions), lack of oxygen to the brain, liver failure, kidney failure, alcohol or **drug overdose**, prolonged exposure to toxic chemicals (solvents, paints, other industrial chemicals), radiation, metabolic diseases, **brain tumor**, increased intracranial pressure, and poor **nutrition**.

HYPOXIC ENCEPHALOPATHY. Hypoxic encephalopathy refers to a lack of oxygen to the entire brain, which typically results in brain damage. Cerebral hypoxia can be caused by **drowning**, low blood pressure, birth injuries, cardiac arrest, strangulation, asphyxiation caused by **smoke inhalation**, severe hemorrhage, **carbon monoxide poisoning**, high altitudes, **choking**, tracheal compression, complications of **anesthesia**, **paralysis** of respiratory muscles, and **respiratory failure**.

Cardiac arrest is the most common condition that causes cerebral hypoxia. When the heart stops pumping, oxygen-rich blood cannot be delivered to vital organs such as the brain. Hypoxia to the brain causes irreversible brain damage after two minutes.

HEPATIC ENCEPHALOPATHY. Hepatic encephalopathy refers to a condition of brain and nervous-system damage caused by liver (hepatic) failure. Impairment of the liver's **detoxification** and functional capabilities causes toxic chemicals such as ammonia and many other impurities to accummulate in the blood; collectively these can damage the nervous system and cause hepatic encephalopathy. Hepatitis and **cirrhosis** are examples of such liver-damaging disorders.

KIDNEY FAILURE. The main function for the kidneys is to eliminate excess fluid and waste material from the blood. When the kidneys lose the ability to filter the blood, dangerous levels of waste products accumulate in the body. Chronic renal failure can be caused by diabetes, analgesic nephropathy (due to long-term use of **aspirin** or **nonsteroidal anti-inflammatory drugs**), kidney diseases (**polycystic kidney disease**, **pyelonephritis**, and **glomerulonephritis**), **renal artery stenosis** (a narrowing of the artery that supplies blood to the kidneys), and **lead poisoning**.

SEVERE INFECTIONS. Severe infections, particularly those that affect the brain, can cause encephalopathy. These include encephalitis, which is an inflammation of the brain typically caused by a virus, and **meningitis**, which is an inflammation of the tissues (meninges) that surround and protect the brain.

CHRONIC ALCOHOL USE. The long-term use of alcohol not only causes destruction of brain cells but can cause cirrhosis of the liver or hepatitis, which results in the destruction of liver cells. Chronic **alcoholism** leads to progressive destruction of liver cells, which can cause end-stage liver failure.

UREMIC ENCEPHALOPATHY. Uremia describes the final stage of progressive **renal insufficiency**, a condition that culminates in uremic encephalopathy, or end-stage kidney failure with neurologic involvement. The cause is unknown and no single metabolite or toxin is responsible for the symptoms; it is an accumulation of several chemicals or toxins in the blood that causes symptoms of encephalopathy.

Symptoms

The hallmark of encephalopathy is altered mental state. In mild cases, hypoxia can cause an altered mental state, which includes symptoms such as motor incoordination, poor judgment, and inattentiveness. Mild cases have no lasting effects. Patients who have severe hypoxia or **anoxia** (total lack of oxygen delivery, usually from cardiac arrest) lose consciousness within seconds. Other symptoms of encephalopathy include lethargy, **nystagmus** (rapid, involuntary eye movement), tremor, **dementia**, seizures, myoclonus (involuntary twitching of a muscle or group of muscles), muscle weakness and atrophy, and loss of ability to speak or swallow. An early and characteristic feature of hepatic encephalopathy is called constitutional **apraxia**, which is the inability to reproduce simple designs such as a star. Patients with liver failure may exhibit a symptom called asterixis, an involuntary jerking tremor of the hands.

Diagnosis

The diagnosis of encephalopathy depends on the presence of acute or chronic liver disease; altered mental state such as confusion, stupor, or **coma**; symptoms of central nervous system damage; and abnormal wave patterns on an encephalogram. Diagnostic tests that may be utilized to establish the diagnosis include, but are not to limited to: **complete blood count**; **liver function tests**; ammonia and glucose levels; lactate levels (often elevated due to impaired tissue perfusion and because of decreased clearance by the liver); arterial blood gases (may reveal hypoxemia); **kidney function tests**; blood cultures (to detect infectious agents); virology testing (for hepatitis); neuroimaging studies; and **ultrasound** studies.

Treatment

Because of the breadth of causes and symptoms of encephalopathies, the treatment team can consist of a broad spectrum of specialists that can include, but is not limited to, an internist, oncologist, pulmonologist, critical care physician, radiologist, hepatologist (specialist in liver diseases), and surgeon. The disorder can also occur in the pediatric ages or even at birth. In these critical situations, specialists in pediatric critical care, a neonatologist, and a perinatologist (specialist in maternal-fetal health) would be involved.

Hypoxia or anoxic encephalopathy is an emergency, and immediate measures are necessary to prevent further damage to the brain and to restore breathing and circulation. It is necessary to treat hepatic encephalopathy early to prevent long-term damage. Specific treatment for hepatic encephalopathy is aimed at eliminating toxic substances and/or treatment of the primary illness that caused the encephalopathy. Elimination of toxins such as ammonia can be accomplished by decreasing absorption of protein from the gut. By giving the patient a compound called lactulose, absorption of ammonia can be decreased. Persons with hepatic encephalopathy should not consume protein, and **constipation** should be avoided. Uremic encephalopathy caused by chronic renal failure is treated with transplantation or dialysis.

Recovery and rehabilitation

For all patients with severe hypoxia or anoxia, recovery is an emergency. Vital functions such as breathing, cardiac function, and delivery of oxygen-rich blood to the brain should be restored within two to five minutes. If anoxia persists for more than two minutes, there will be permanent and severe damage to the brain.

Clinical trials

The latest information can be obtained online from the website http://www.clinicaltrials.gov.

Prognosis

The outcome for patients who present with symptoms of encephalopathy depends on the cause. If the cause can be corrected in time, the outcome can be favorable. However, if encephalopathy is a manifestation

WWW.BOOKBAZ.IR

of more advanced chronic disease, or if it is part of a rapidly fulminating disorder, the outcome can be poor and death may ensue.

Persons who present with encephalopathy have advanced disease or the beginning of an advanced disease process. Vigilance on the part of the primary care provider is necessary to take all precautions to prevent this process.

Encopresis

Definition

Encopresis is repeatedly having bowel movements in places other than the toilet after the age when bowel control can normally be expected.

Description

Most children have established bowel control by the time they are four years old. After that age, when they repeatedly have bowel movements in inappropriate places, they may have encopresis. In the United States, encopresis affects 1–2% of children under age 10. About 80% of these are boys.

Encopresis can be either involuntary or voluntary. Involuntary encopresis is related to **constipation**, passing hard painful feces, and difficult bowel movements. Often children with involuntary encopresis stain their underpants with liquid feces. They are usually unaware that this has happened. Voluntary encopresis is much less common and is associated with behavioral or psychological problems. Both types of encopresis occur most often when the child is awake, rather than at night.

Causes and symptoms

Although a few children experience encopresis because of malformations of the lower bowel and anus or irritable bowel disease, most have no physical problems to explain this disorder. Constipation is present in about 80% of children who experience involuntary encopresis. As feces moves through the large intestine, water is removed. The longer the feces stays in the large intestine, the more water is removed, and the harder the feces becomes. The result can be hard or painful bowel movements. In response, children may start to hold back when they feel the urge to eliminate in order to avoid **pain**. This starts a cycle of constipation that results in retentive encopresis.

Once elimination is avoided, the bowel becomes full of hard feces. This stretches the large intestine. Eventually the intestine becomes so stretched that liquid feces backed up behind the blockage is able to leak around the hard feces. Children with this type of encopresis do not feel the urge to have a bowel movement and are often surprised when their pants are stained with foul smelling liquid feces. This leakage of feces is called overflow incontinence. Parents sometimes mistake this soiling for **diarrhea**, because the feces expelled is liquid. Every so often, children with involuntary encopresis may pass large stools, sometimes with volumes big enough to clog the toilet, but the relief this brings is temporary.

Although about 95% of encopresis is involuntary, some children intentionally withhold bowel movements. The American Psychiatric Association (APA) recognizes voluntary encopresis without constipation as a psychological disorder. This disorder is said to occur when a child who has control over his bowel

movements chooses to have them in an inappropriate place. The feces is a normal consistency, not hard. Sometimes it is smeared in an obvious place, but it may also be hidden from adults.

Voluntary encopresis may result from a power struggle between caregivers and the child during toilet training, or the child may have developed an unusual fear of the toilet. It is also associated with **oppositional defiant disorder** (ODD), **conduct disorder**, **sexual abuse**, and high levels of psychological **stress**. For example, children who were separated from their parents during World War II were reported to have a high rate of encopresis. However, parents and caregivers should be aware that very few children soil intentionally and most do not have a behavioral or psychological problem and should not be punished for their soiling accidents.

Diagnosis

Diagnosis is based primarily on the child's history of inappropriate bowel movements. Physical examinations are almost always normal, except for a mass of hard feces blocking the lower intestine. Other physical causes of soiling, such as illness, reaction to medication, **food allergies**, and physical disabilities, may also be ruled out through history and a **physical examination**. In addition, to be diagnosed with encopresis the child must be old enough to establish regular bowel control—usually chronologically and developmentally at least four years of age.

Treatment

The goal of treatment is to establish regular, soft, pain free bowel movements in the toilet. First the physician tries to determine the cause of encopresis, whether physical or psychological. Regardless of the cause, the bowel must be emptied of hard, impacted feces This can be done using an enema, **laxatives**, and/or stool softeners such as mineral oil. **Enemas** and laxatives should be used only at a doctor's recommendation.

Next, the child is given stool softeners to keep feces soft and to give the stretched intestine time to shrink back to its normal size. This shrinking process may take several months, during which time stool softeners may need to be used regularly. Children also need two or three regularly scheduled toilet sits daily in an effort to establish consistent bowel habits. These toilet sits are often more effective if done after meals. Maintaining soft, easy-to-pass stools is also important if the child is afraid of the toilet because of past painful bowel movements. A child psychologist or psychiatrist can suggest treatment for the rare child with serious behavioral problems such as smearing or hiding feces.

KEY TERMS

Feces—Waste products eliminated from the large intestine; excrement.

Incontinence—The inability to control the release of urine or feces.

Laxative—Material that encourages a bowel movement.

Stools—Feces; bowel movements.

Alternatives

Many herbal stool softeners and laxatives are available as both tablets and liquids. Psyllium, the seed of several plants of the genus *Plantago* is one of the most effective. Other natural remedies for constipation include castor seed oil (*Ricinus communis*), senna (*Cassia senna* or *Senna alexandrina*), and dong quai (*Angelica polymorpha* or *Angelica sinensis*).

Prognosis

For almost all children, once constipation is controlled, the problem of soiling disappears. This may take several months, and relapses may occur, but with effective prevention strategies, encopresis can be eliminated. Children who are in a power struggle over toileting usually outgrow their desire to have bowel movements in inappropriate places. The prognosis for children with serious behavioral and psychological problems that result in smearing or hiding feces depends largely on resolving the underlying problems.

Prevention

The best way to prevent encopresis is to prevent constipation. Methods of preventing constipation include:

- increasing the amount of liquids, especially water, the child drinks
- adding high fiber foods to the diet (e.g. dried beans, fresh fruits and vegetables, whole wheat bread and pasta, popcorn)
- establishing regular bowel habits
- limiting the child's intake of dairy products (e.g. milk, cheese, yogurt, ice cream) that promote constipation

WWW.BOOKBAZ.IR

• treating constipation promptly with stool softeners, so that it does not become worse

Plaque is removed from the carotid artery by clamping the artery, cutting the plaque out, and closing the opening back up. *(Illustration by Argosy, Inc. © Cengage Learning®.)*

Endarterectomy

Definition

Endarterectomy is an operation to remove or bypass the fatty deposits, or blockage, in an artery narrowed by the buildup of fatty tissue (atherosclerosis).

Purpose

Removing the fatty deposits restores normal blood flow to the part of the body supplied by the artery. An endarterectomy is performed to treat cerebrovascular disease in which there is a serious reduction of blood supply to the brain (carotid endarterectomy), or to treat **peripheral vascular disease** (impaired blood supply to the legs).

Endarterectomy is most often performed on one of the two main arteries in the neck (the carotids) opening the narrowed arteries leading to the brain. When performed by an experienced surgeon, the practice is extremely effective, reducing the risk of **stroke** by up to 70%. Recent studies indicate it is effective in preventing stroke, even among those patients who had no warning signs except narrowed arteries detected by their doctors on a routine exam.

Precautions

Before the surgery, a full medical exam is usually done to assess any specific health problems, such as diabetes, high blood pressure, **heart disease**, or stroke. If possible, reversible health problems, such as cigarette **smoking** or being overweight, should be corrected.

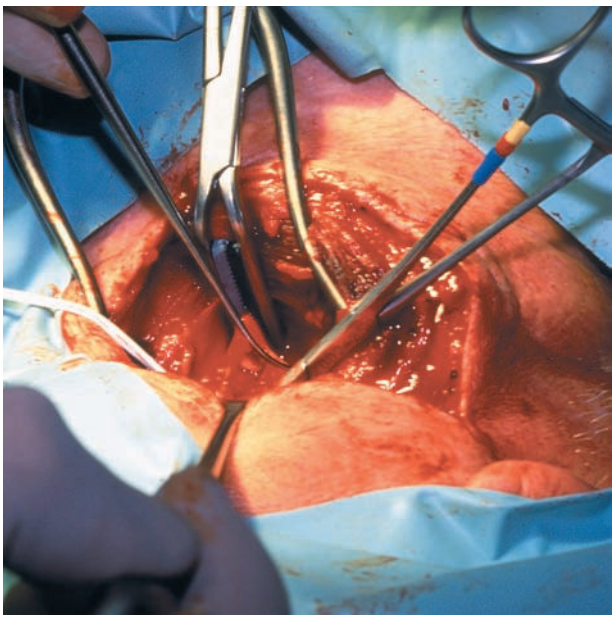
Description

Carotid artery disease

Every person has four carotid arteries (the internal and external carotids on each side of the neck) through which blood from the heart moves into the brain. If one of these arteries becomes blocked by fat and **cholesterol**, the patient may have a range of symptoms, including:

- weakness in one arm, leg, half of the face, or one entire side of the body
- numbness or tingling
- paralysis of an arm, leg, or face
- slurred speech
- dizziness
- confusion, fainting, or coma
- stroke

Removing this fatty buildup, or bypassing a blocked segment, may restore blood flow to the brain,



In this procedure, surgeons are removing plaque from the carotid artery. *(Custom Medical Stock Photo, Inc.)*

eliminate or decrease the symptoms, and lessen the risk of a stroke.

Peripheral vascular disease

When the blood vessels in the legs (and sometimes the arms) become narrowed, this can restrict blood flow and cause **pain** in the affected area. In severe cases, the tissue may die, requiring **amputation**.

The narrowing is usually caused by buildup of fatty plaques in the vessels, often as the result of smoking, high blood pressure, or poorly-controlled **diabetes mellitus**. The vessels usually narrow slowly, but it's possible for a blood clot to form quickly, causing sudden severe pain in the affected leg or arm.

Procedure

Endarterectomy is a delicate operation that may require several hours. The surgeon begins by making an incision over the blocked artery and inserting a tube above and below the blockage to redirect the blood flow while the artery is opened.

Next, the surgeon removes the fat and cholesterol buildup, along with any **blood clots** that have formed, with a blunt dissecting instrument. Then the surgeon bathes the clean wall in salt solution combined with heparin, an anticoagulant. Then the surgeon stitches the artery just enough so that the bypass shunt tube can be removed, and then he/she stitches the artery completely closed. After checking to make sure no blood is leaking, the surgeon next closes the skin incision with stitches.

The operation should improve symptoms, although its long-term effects may be more limited, since arterial narrowing is rarely confined to one area of one artery. If narrowing is a problem throughout the body, arterial **reconstructive surgery** may be required.

The total cost of an endarterectomy, including diagnostic tests, surgery, hospitalization, and follow-up care, will vary according to hospital, doctor, and area of the country where the operation is performed, but a patient can expect to pay in the range of $15,000. Patients who are very young, very old, or very ill, or who need more extensive surgery, may require more expensive treatment.

Preparation

Before surgery, the doctor pinpoints the location of the narrowed artery with an x-ray procedure called **angiography**. For surgery to be effective, the degree of narrowing should be at least 70%, but it should not be total. Patients undergoing angiography are given a local anesthetic, but the endarterectomy itself requires the use of a general **anesthesia**.

Aftercare

After the surgery, the patient spends the first two days lying flat in bed. Patients who have had carotid endarterectomy should not bend the neck sharply during this time. Because the blood flow to the brain is now greatly increased, patients may experience a brief but severe **headache**, or lightheadedness. There may be a slight loss of sensation in the skin, or maybe a droop in the mouth, if any of the nerves in the neck were lightly bruised during surgery. In time, this should correct itself.

Risks

The amount of risk depends on the hospital, the skill of the surgeon, and the severity of underlying disease. Patients who have just had an acute stroke are at greatest risk. During carotid artery surgery, blood flow is interrupted through the artery, so that **paralysis** and other stroke symptoms may occur. These may resolve after surgery, or may result in permanent stroke. Paralysis is usually one-sided; other stroke symptoms may include loss of half the

WWW.BOOKBAZ.IR

KEY TERMS

Carotid arteries—The four principal arteries of the neck and head. There are two common carotid arteries, each of which divides into the two main branches (internal and external).

Diabetes mellitus—A disorder in which the pancreas does not produce enough (or any) insulin. As a result, the blood levels of sugar become very high. Among other things, diabetes can lead to the breakdown of small blood vessels and a high risk of atherosclerosis and high blood pressure.

Stroke—Damage to the part of the brain caused by an interruption of the blood supply. In some cases, small pieces of plaque in the carotid artery may break loose and block an artery in the brain. A narrowed carotid artery also can be the source of blood clots travelling to the brain, or the artery can become completely clogged, blocking all blood flow to the brain.

field of vision, loss of sensation, double vision, speech problems, and personality changes. Risks of endarterectomy to treat either carotid artery or peripheral **vascular disease** include:

- reactions to anesthesia
- bleeding
- infection
- blood clots

Results

The results after successful surgery are usually striking. The newly opened artery should help to restore normal blood flow. In carotid endarterectomy, surgery should prevent the risk of brain damage and stroke. However, the buildup of fat and cholesterol usually affects all arteries, not just the one that was operated on. Affected arteries in other parts of the body may be equally clogged and potentially dangerous. Even arteries that were operated electively will likely begin to clog up again after the surgery.

For this reason, lifestyle changes (no smoking, low fat, low cholesterol diet) are important, especially if diet and lifestyle contributed to the development of the problem in the first place.

Endemic syphilis *see* **Bejel**

Endocardial resection *see* **Myocardial resection**

Endocarditis

Definition

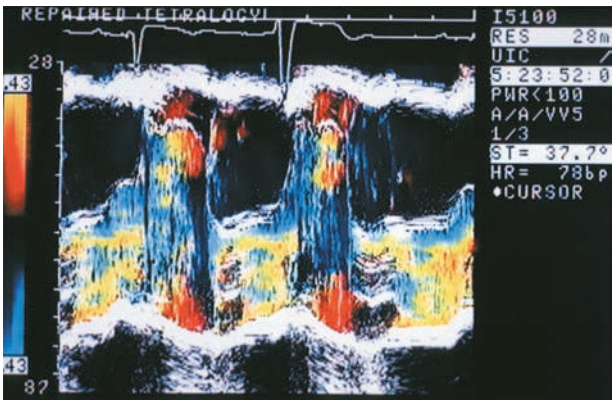
The endocardium is the inner lining of the heart muscle, which also covers the heart valves. When the endocardium becomes damaged, bacteria from the bloodstream can become lodged on the heart valves or heart lining. The resulting infection is known as endocarditis.

Description

The endocardium lines all four chambers of the heart—two at the top (the right and left atria) and two at the bottom (the right and left ventricles)–through which blood passes as the heart beats. It also covers the four valves (the tricuspid valve, the pulmonary valve, the mitral valve, and the aortic valve), which normally open and close to allow the blood to flow in only one direction through the heart during each contraction.

For the heart to pump blood efficiently, the four chambers must contract and relax, and the four valves must open and close, in a well coordinated fashion. By damaging the valves or the walls of the heart chambers, endocarditis can interfere with the ability of the heart to do its job.

Endocarditis rarely occurs in people with healthy, normal hearts. Rather, it most commonly occurs when there is damage to the endocardium. The endocardium may be affected by a congenital heart defect, such as **mitral valve prolapse**, in which blood leaks through a poorly functioning mitral valve back into the heart. It may also be damaged by a prior scarring of the heart muscle, such as **rheumatic fever**, or replacement of a heart valve. Any of these conditions can damage the endocardium and make it more susceptible to infection.



This echocardiogram shows an aortic regurgitation due to endocarditis, an infection of the lining membrane of the cardiac chambers. *(Custom Medical Stock Photo, Inc.)*

Bacteria can get into the bloodstream (a condition known as **bacteremia**) in a number of different ways: It may spread from a localized infection such as a **urinary tract infection**, **pneumonia**, or skin infection or get into the bloodstream as a result of certain medical conditions, such as severe **periodontal disease**, **colon cancer**, or inflammatory bowel disease. It can enter the bloodstream during minor procedures, such as periodontal surgery, tooth extractions, teeth cleaning, tonsil removal, prostate removal, or endoscopic examination. It can also be introduced through in-dwelling catheters, which are used for intravenous medications, intravenous feeding, or dialysis. In people who use intravenous drugs, the bacteria can enter the bloodstream through unsterilized, contaminated needles and syringes. (People who are prone to endocarditis generally need to take prescribed **antibiotics** before certain surgical or dental procedures to help prevent this infection.)

If not discovered and treated, infective endocarditis can permanently damage the heart muscle, especially the valves. For the heart to work properly, all four valves must be functioning well, opening at the right time to let blood flow in the right direction and closing at the right time to keep the blood from flowing in the wrong direction. If the valve is damaged, this may allow blood to flow backward—a condition known as regurgitation. As a result of a poorly functioning valve, the heart muscle has to work harder to pump blood and may become weakened, leading to **heart failure**. Heart failure is a chronic condition in which the heart is unable to pump blood well enough to supply blood adequately to the body.

Another danger associated with endocarditis is that the vegetation formed by bacteria colonizing on heart valves may break off, forming emboli. These emboli may travel through the circulation and become lodged in blood vessels. By blocking the flow of blood, emboli can starve various tissues of nutrients and oxygen, damaging them. For instance, an embolus lodged in the blood vessels of the lungs may cause pneumonia-like symptoms. An embolus may also affect the brain, damaging nerve tissue, or the kidneys, causing **kidney disease**. Emboli may also weaken the tiny blood vessels called capillaries, causing hemorrhages (leaking blood vessels) throughout the body.

Causes and symptoms

Most cases of infective endocarditis occur in people between the ages of 15 and 60, with a median age at onset of about 50 years. Men are affected about twice as often as women. Other factors that put people at increased risk for endocarditis are congenital heart problems, heart surgery, previous episodes of endocarditis, and intravenous drug use.

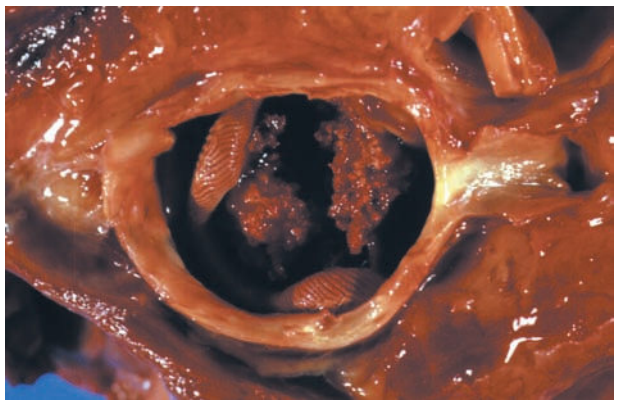
While there is no single specific symptom of endocarditis, a number of symptoms may be present. The most common symptom is a mild **fever**, which rarely goes above 102°F (38.9°C). Other symptoms include chills, weakness, **cough**, trouble breathing, headaches, aching joints, and loss of appetite.

Emboli may also cause a variety of symptoms, depending on their location. Emboli throughout the body may cause Osler's nodes, small, reddish, painful bumps most commonly found on the inside of fingers and toes. Emboli may also cause petechiae, tiny purple or red spots on the skin, resulting from hemorrhages under the skin's surface. Tiny hemorrhages resembling splinters may also appear under the fingernails or toenails. If emboli become lodged in the blood vessels of the lungs, they may cause coughing or **shortness of breath**. Emboli lodged in the brain may cause symptoms of a mini-stroke, such as numbness, weakness, or **paralysis** on one side of the body or sudden vision loss or double vision. Emboli may also damage the kidneys, causing blood to appear in the urine. Sometimes the capillaries on the surface of the spleen rupture, causing the spleen to become enlarged and tender to the touch. Anyone experiencing any of these symptoms should seek medical help immediately.

Diagnosis

Doctors begin the diagnosis by taking a history and asking the patient about the symptoms. During a

WWW.BOOKBAZ.IR



A close-up view of an infected artificial heart valve showing bacterial endocarditis (the granulated tissue at center of image). When infection occurs early after surgery, it is likely that organisms have gained entry during the operative period. This type of infection is usually caused by *Staphylococcus epidermidis* and *S. aureus* and is treated with antibiotic drugs. *(Dr. E. Walker/Photo Researchers, Inc.)*

physical examination, the doctor may also uncover signs such as fever, an enlarged spleen, signs of kidney disease, or hemorrhaging. Listening to the patient's chest with a stethoscope, the doctor may also hear a heart murmur. A heart murmur may indicate abnormal flow of blood through one of the heart chambers or valves.

Doctors take a sample of the patient's blood to test it for bacteria and other microorganisms that may be causing the infection. They usually also use a test called **echocardiography**, which uses **ultrasound** waves to make images of the heart, to check for abnormalities in the structure of the heart wall or valves. One of the tell-tale signs they look for in echocardiography is vegetation, the abnormal growth of tissue around a valve composed of blood platelets, bacteria, and a clotting protein called fibrin. Another tell-tale sign is regurgitation, or the backward flow of blood, through one of the heart valves. A normal echocardiogram does not exclude the possibility of endocarditis, but an abnormal echocardiogram can confirm its presence. If an echocardiogram cannot be done or its results are inconclusive, a modified technique called **transesophageal echocardiography** is sometimes performed. Transesophageal echocardiography involves passing an ultrasound device into the esophagus to get a clearer image of the heart.

Treatment

When doctors suspect infective endocarditis, they will admit the patient to a hospital and begin treating the infection before they even have the results of the **blood culture**. Their choice of antibiotics depends on what the most likely infecting microorganism is. Once the results of the blood culture become available, the doctor can adjust the medications, using specific antibiotics known to be effective against the specific microorganism involved.

In recent years, the treatment of endocarditis has become more complicated as a result of **antibiotic resistance**. Over the past few years, especially as antibiotics have been overprescribed, more and more strains of bacteria have become increasingly resistant to a wider range of antibiotics. For this reason, doctors may need to try a few different types of antibiotics—or even a combination of antibiotics—to successfully treat the infection. Antibiotics are usually given for about one month, but may need to be given for an even longer period of time if the infection is resistant to treatment.

Once the fever and the worst of the symptoms have gone away, the patient may be able to continue antibiotic therapy at home. During this time, the patient should make regular visits to the health care team for further testing and physical examination to make sure that the antibiotic therapy is working, that it is not causing adverse side effects, and that there are no complications such as emboli or heart failure. The patient should alert the health-care team to any symptoms that could indicate serious complications: For instance, trouble breathing or swelling in the legs could indicate **congestive heart failure**. **Headache**, joint **pain**, blood in the urine, or **stroke** symptoms could indicate an embolus, and fever and chills could indicate that the treatment is not working and the infection is worsening. Finally, **diarrhea**, rash, **itching**, or joint pain may suggest a bad reaction to the antibiotics. Anyone experiencing any of these symptoms should alert the health care team immediately.

In some cases, surgery may be needed. These include cases of congestive heart failure, recurring emboli, infection that does not respond to treatment, poorly functioning heart valves, and endocarditis involving prosthetic (artificial) valves. The most common surgical treatment involves cutting away (debriding) damaged tissue and replacing the damaged valve.

Prognosis

If left untreated, infective endocarditis continues to progress and is always fatal. However, if it is diagnosed and properly treated within the first six weeks of infection, the infection can be completely cured in about 90% of the cases. The prognosis depends on a number of factors, such as the patient's age and overall physical condition, the severity of the

KEY TERMS

Aortic valve—The valve between the left ventricle of the heart and the aorta.

Bacteremia—An infection caused by bacteria in the blood.

Congestive heart failure—A condition in which the heart muscle cannot pump blood as efficiently as it should.

Echocardiography—A diagnostic test using reflected sound waves to study the structure and motion of the heart muscle.

Embolus—A bit of foreign material, such as gas, a piece of tissue, or tiny clot, that travels in the circulation until it becomes lodged in a blood vessel.

Endocardium—The inner wall of the heart muscle, which also covers the heart valves.

Mitral valve—The valve between the left atrium and the left ventricle of the heart.

Osler's nodes—Small, raised, reddish, tender areas associated with endocarditis, commonly found inside the fingers or toes.

Petechiae—Tiny purple or red spots on the skin associated with endocarditis, resulting from hemorrhages under the skin's surface.

Pulmonary valve—The valve between the right ventricle of the heart and the pulmonary artery.

Transducer—A device that converts electrical signals into ultrasound waves and ultrasound waves back into electrical impulses.

Transesophageal echocardiography—A diagnostic test using an ultrasound device, passed into the esophagus of the patient, to create a clear image of the heart muscle.

Tricuspid valve—The valve between the right atrium and the right ventricle of the heart.

Vegetation—An abnormal growth of tissue around a valve, composed of blood platelets, bacteria, and a protein involved in clotting.

diseases involved, the exact site of the infection, how vulnerable the microorganisms are to antibiotics, and what kind of complications the endocarditis may be causing.

Prevention

Some people are especially prone to endocarditis. These include people with past episodes of endocarditis, those with congenital heart problems or heart damage from rheumatic fever, and those with artificial heart valves. Intravenous drug users are also at increased risk. Anyone who falls into a high-risk category should alert his or her health-care professionals before undergoing any surgical or dental procedures. High-risk patients must be treated in advance with antibiotics before these procedures to minimize the risk of infection.

Endocrine pancreatic cancer *see* **Pancreatic cancer, endocrine**

Endometrial biopsy

Definition

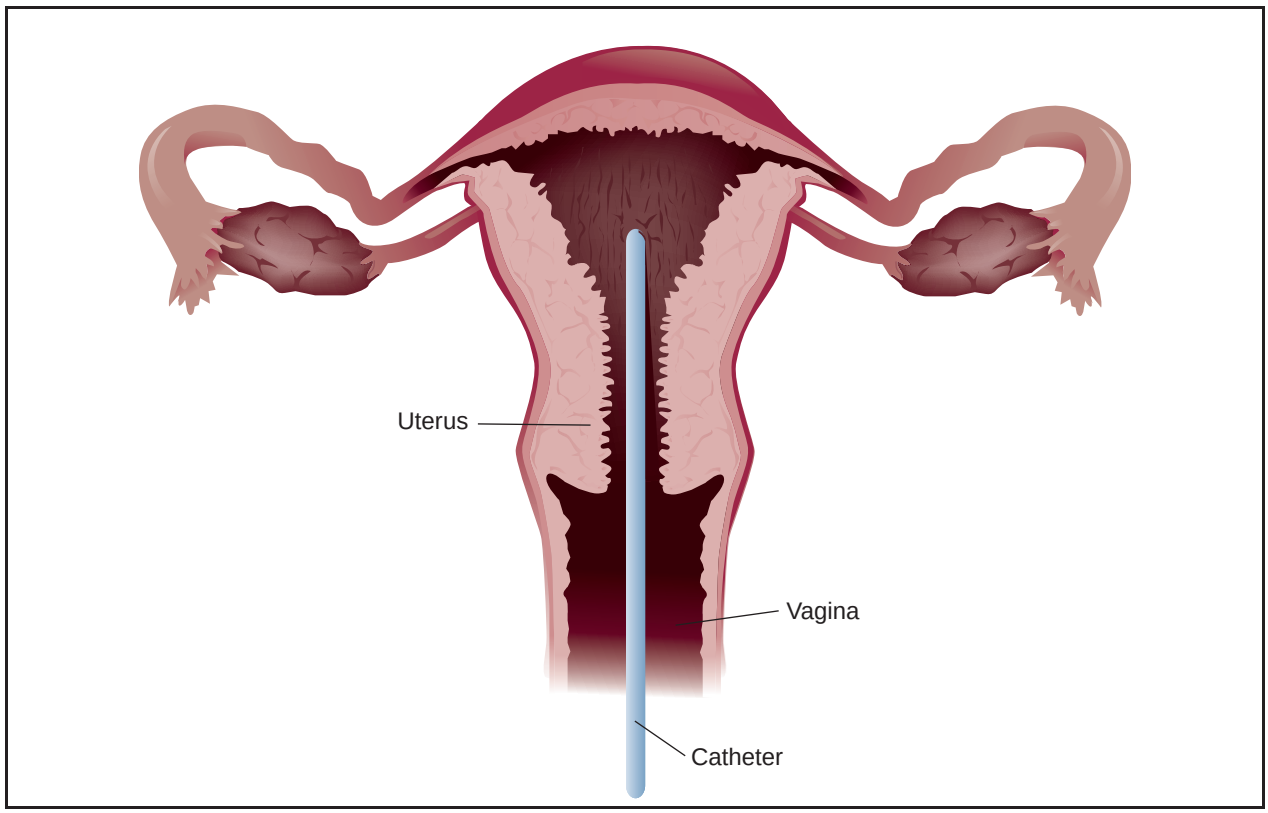
Endometrial biopsy is a procedure in which a sample of the endometrium (tissue lining the inside of the uterus) is removed for microscopic examination.

Purpose

The test is most often performed to find out the cause of abnormal uterine bleeding. Abnormal bleeding includes bleeding between menstrual periods, excessive bleeding during a menstrual period, or bleeding after **menopause**. Since abnormal uterine bleeding can indicate cancer, an endometrial biopsy is done to rule out **endometrial cancer** or hyperplasia (a potentially precancerous condition).

Endometrial biopsies are also done as a screening test for endometrial cancer in postmenopausal women on **hormone replacement therapy**. Hormone replacement therapy usually requires a woman to take estrogen and progesterone. An endometrial biopsy is particularly useful in cases where postmenopausal women take

WWW.BOOKBAZ.IR



A catheter is inserted into the uterus to remove uterine cells for further examination. *(Illustration by Argosy, Inc. © Cengage Learning®.)*

estrogen, but cannot take progesterone. Estrogen in the system without the balancing effect of progesterone has been linked to an increased risk of endometrial cancer.

An endometrial biopsy can be used as part of an **infertility** exam to rule out problems with the development of the endometrium. This condition is called luteal phase defect and can cause the endometrium to not support a **pregnancy**. An endometrial biopsy can also be used to evaluate the problem of repeated early miscarriages.

Description

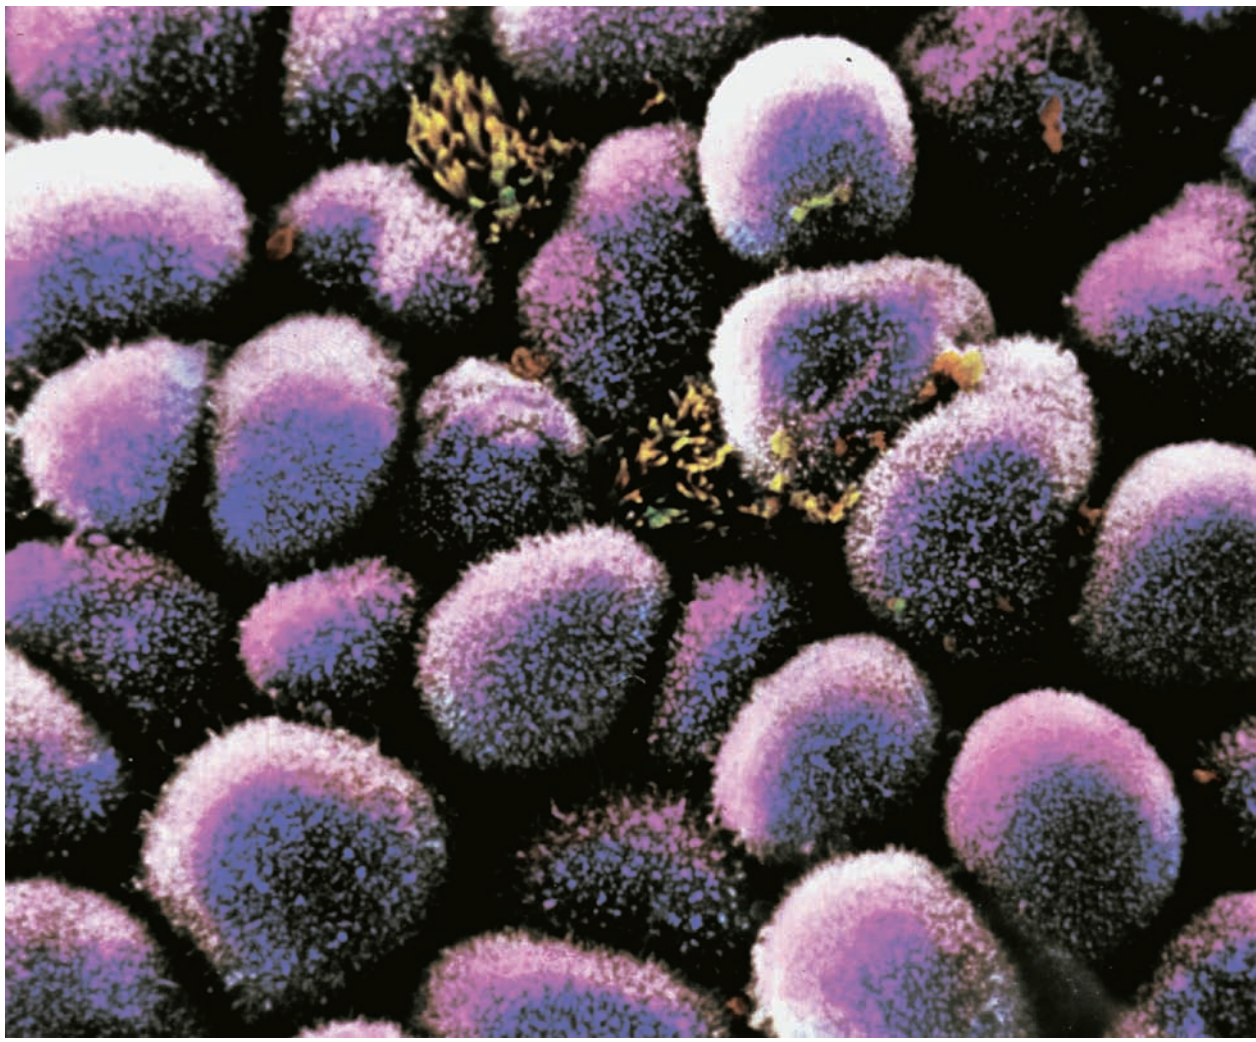
The test is performed by a doctor who specializes in women's reproductive health (an obstetrician/gynecologist). The test is performed either in the doctor's office or in a local hospital. The patient may be asked to take **pain** medication (like ibuprofen) an hour or so before the procedure. A local anesthetic may be injected into the cervix in order to decrease pain and discomfort during the procedure.

The woman is asked to lie on her back with knees apart and feet in stirrups. The doctor first conducts a thorough exam of the pelvic region, including the vulva (the external genitals), vagina, and uterus. A speculum (an instrument that is used to hold the walls of the vagina open) is inserted into the vagina and then a small, hollow plastic tube is passed into the uterine cavity. A small piece of the uterine lining is evacuated with a plunger attached to the tube. Once the sample is obtained, the instruments are removed. The sample is sent to the laboratory for microscopic examination.

The patient may experience some pain when the cervix is grasped. The patient may also feel some cramping, pressure, and discomfort when the instruments are inserted into the uterus and the tissue sample is collected.

Preparation

For the small number of endometrial biopsies that are done as part of infertility testing, a pregnancy test is often performed before the procedure. Since the biopsy is performed late in the menstrual cycle, it is possible that the woman may be pregnant.



A micrograph image of the internal human uterine wall depicting the mucosa, or endometrium. *(Custom Medical Stock Photo, Inc.)*

Aftercare

The biopsy may cause a small amount of bleeding (spotting). The woman can resume normal activities right away. If cramping becomes severe, heavy bleeding occurs, or the woman develops a high temperature, the doctor should be notified immediately.

If the test is being done to determine the cause of infertility, the onset of the menstrual period following the biopsy should be reported to the doctor. This will allow the doctor to correctly predict if the endometrium has been developing at the expected rate.

Risks

The risks of an endometrial biopsy are very small. There is a possibility that prolonged bleeding may occur after the procedure. There is also a slight chance of infection. Very rarely, there are instances when the uterus is pierced (perforated) or the cervix is torn because of the biopsy.

Results

Most biopsies are done to rule out endometrial cancer or endometrial hyperplasia. A normal result shows no cancerous or precancerous cells. Normal results also show that the uterine lining is changing at the proper rate. If it is, then the results of the biopsy are said to be "in-phase" because the tissue looks appropriate and has developed normally for the late phase of the menstrual cycle.

If the endometrium is not developing at the appropriate rate, the results are said to be "out-of-phase" or

WWW.BOOKBAZ.IR

KEY TERMS

Biopsy—Surgical removal and microscopic examination of living tissue for diagnostic purposes.

Cervix—The opening of the uterus extending into the vagina.

Endometrium—The layer lining the inner cavity of the uterus; this layer changes daily throughout the menstrual cycle.

Uterus—The hollow, muscular female organ that supports the development and nourishment of the unborn baby during pregnancy.

abnormal. The endometrium has not developed appropriately and cannot support a pregnancy. This condition is called luteal phase defect and may need to be treated with progesterone.

Abnormal appearance of the cells forming the uterine tissue could indicate uterine cancer, or the presence of fibroids or polyps in the uterus.

Endometrial cancer

Definition

Endometrial cancer develops when the cells that make up the inner lining of the uterus (the endometrium) become abnormal and grow uncontrollably. It is also called cancer of the uterine corpus.

Description

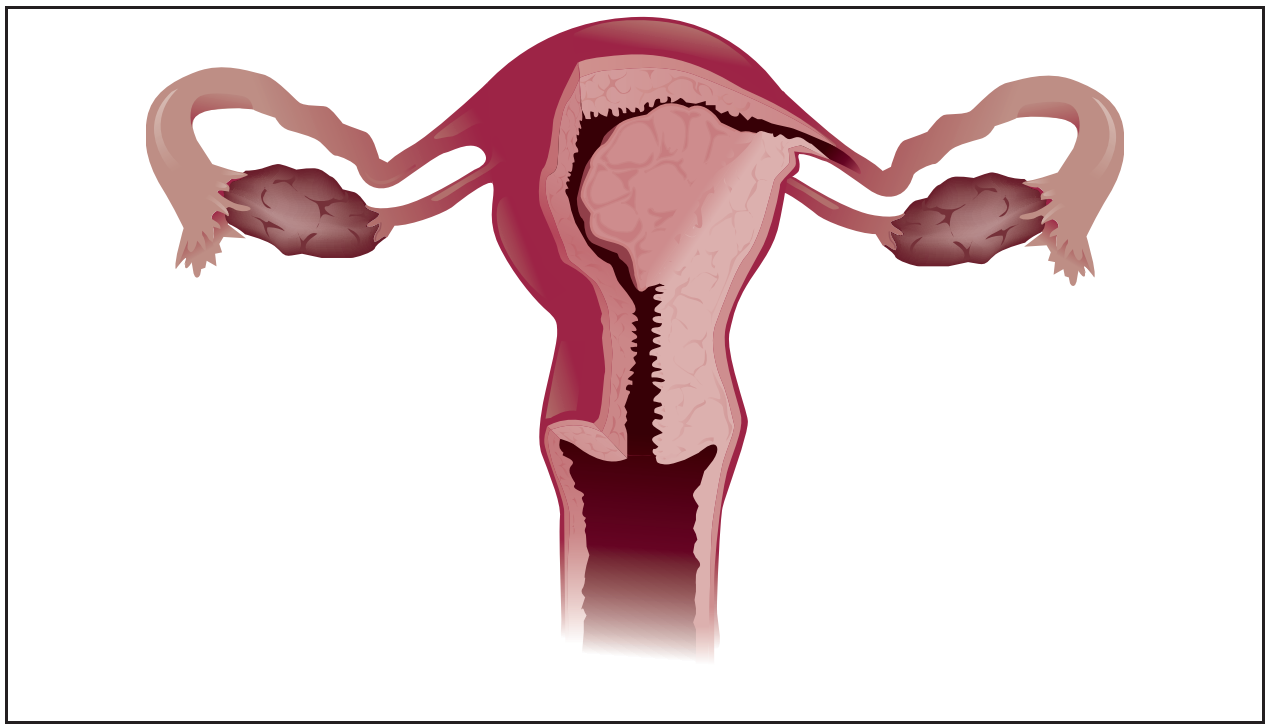
The uterus, or womb, is the hollow organ in the human female that supports the development of the unborn baby during **pregnancy**. The uterus has a thick muscular wall and an inner lining called the endometrium. The endometrium is very sensitive to hormones, and it changes daily during the menstrual cycle. The endometrium is designed to provide an ideal environment for the fertilized egg to implant and begin to grow. If pregnancy does not occur, the endometrium is shed, causing the normal menstrual period.

More than 95% of uterine cancers arise in the endometrium. The most common type of uterine cancer is an adenocarcinoma, a cancer that originates in glandular tissue. It arises from an abnormal multiplication of endometrial cells (atypical adenomatous hyperplasia) and is made up of mature specialized cells (well-differentiated). Less commonly, endometrial cancer arises without a preceding hyperplasia and is made up of poorly differentiated cells. The more common of these types are the papillary serous and clear cell carcinomas. Poorly differentiated endometrial cancers are often associated with a less promising prognosis and are treated more aggressively.

A small percentage (about 4%) of endometrial cancers form in the muscle or connective tissue layers of the uterus rather than in the endometrial lining. These cancers are called uterine **sarcomas**; they have a different prognosis from endometrial cancers and are treated differently.

Demographics

Endometrial cancer (also called uterine cancer) is the fourth most common type of cancer overall among women and the most common gynecologic cancer among women in the United States. Approximately 52,630 women are diagnosed with endometrial cancer each year. In 2014, the American Cancer Society predicted that approximately 8,590 women would die from this cancer that year. Endometrial cancer is rare in women younger than 45; more than half of all endometrial cancer diagnoses occur in women who are between ages 55 and 74. The average age at diagnosis is 60. An



Cancer located in the uterus. *(Illustration by Argosy, Inc. © Cengage Learning®.)*

American woman has one chance in 37 of developing endometrial cancer during her lifetime.

The highest incidence of endometrial cancer in the United States is in Caucasians, Hawaiians, Japanese, and African Americans. American Indians, Koreans, and Vietnamese have the lowest incidence. African American and Hawaiian women are more likely to be diagnosed with advanced cancer and, therefore, have a higher risk of dying from the disease.

Causes and symptoms

Although the exact cause of endometrial cancer is unknown, it is clear that high levels of estrogen can lead to abnormal growth of the endometrium when not balanced by progesterone. Factors that increase a woman's risk of developing endometrial cancer are:

- Age. The risk is considerably higher in women who are over the age of 50 and have completed menopause.
- Obesity. Being overweight is a very strong risk factor for this cancer. Fatty tissue can change other normal body chemicals into estrogen, which can promote endometrial cancer.
- Estrogen replacement therapy. Women receiving estrogen supplements after menopause have a 12 times higher risk of getting endometrial cancer if progesterone is not taken simultaneously.
- Diabetes. Diabetics have twice the risk of developing endometrial cancer as nondiabetic women. It is not clear whether this risk is due to the fact that many diabetics are also obese and hypertensive.
- Hypertension. High blood pressure (hypertension) is also considered a risk factor for uterine cancer.
- Endometrial hyperplasia. Endometrial hyperplasia is a condition in which the endometrium produces an overgrowth of cells known as hyperplasia. Hyperplasia is not itself cancerous but can develop into cancer.
- Irregular menstrual periods. There is interaction between the hormones estrogen and progesterone during the menstrual cycle. Women who do not ovulate regularly are exposed to high estrogen levels for longer periods of time. If a woman does not ovulate regularly, this delicate balance is upset and may increase her chances of getting uterine cancer.
- Early first menstruation or late menopause. Having the first period at a young age (the mean age of menarche is 12.16 years in African American girls and 12.88 years in Caucasian girls) or going through menopause at a late age (over age 55) seems to put women at a slightly higher risk of developing endometrial cancer.
- Tamoxifen. This drug, which is used to treat or prevent breast cancer, increases a woman's chance of

WWW.BOOKBAZ.IR

KEY TERMS

Adenocarcinoma—A type of cancer that originates in glandular tissue. Most endometrial cancers are adenocarcinomas.

Biopsy—Removal of a small sample of tissue for examination under a microscope; used for the diagnosis and treatment of cancer and precancerous conditions.

Brachytherapy—A form of radiation therapy in which small pellets of radioactive material are placed inside or near the area to be treated. It is also known as internal radiation therapy or sealed-source radiotherapy.

Cystoscopy—A diagnostic procedure in which a hollow lighted tube (cystoscope) is used to look inside the bladder and the urethra.

Debulking—The surgical removal of part of a cancerous tumor that cannot be completely excised, in order to improve the effectiveness of radiation therapy or chemotherapy.

Endometrial hyperplasia—A condition in which the endometrium produces an overgrowth of cells during the menstrual cycle. It is not cancerous in itself but is a risk factor for endometrial cancer.

Endometrium—The inner mucous membrane that lines the uterus in humans and other mammals.

Estrogen—The primary female sex hormone, responsible for the buildup of endometrial tissue, the development of secondary sexual characteristics in women, and regulation of other aspects of the menstrual cycle.

Hysterectomy—Surgical removal of the uterus.

Lymph nodes—Small round glands, located throughout the body, that filter the lymphatic fluid; part of the body's immune system.

Pap (Papanicolaou) smear—Pap test; removal of cervical cells to screen for cancer. The test was invented by and named for Greek physician George Papanicolaou, who was an early pioneer in cancer detection.

Progesterone—A steroid hormone produced in the ovaries, involved in the menstrual cycle and pregnancy. Its levels rise during pregnancy, when it is produced by the placenta instead of the ovaries.

Progestins—Synthetic hormones resembling progesterone used in the treatment of advanced endometrial cancer.

Salpingo-oophorectomy—Surgical removal of the fallopian tubes and the ovaries.

Vaginal stenosis—Narrowing of the vagina due to a buildup of scar tissue.

developing endometrial cancer. Tamoxifen users tend to have more advanced endometrial cancer with an associated poorer survival rate than those who do not take the drug. In many cases, however, the value of tamoxifen for treating breast cancer and for preventing that cancer from spreading far outweighs the small risk (one in 500) of getting endometrial cancer.

- Family history. Some studies suggest that endometrial cancer runs in certain families. Women with inherited mutations in the *BRCA1* and *BRCA2* genes are at a higher risk of developing breast, ovarian, and other gynecologic cancers. Those with any of the genes associated with hereditary nonpolyposis colorectal cancer (HNPCC) have a higher risk of developing endometrial cancer. HNPCC is also called Lynch syndrome. As of 2014, there were at least seven identified genes whose mutations can cause Lynch syndrome and increase a woman's risk of endometrial as well as colorectal cancer: *MLH1*, *MSH2*, *MLH3*, *MSH6*, *TGBR2*, *PMS1*, and *PMS2*.
- Personal history of breast, ovarian, or colon cancer. Women who have a history of these other types of cancer are at an increased risk of developing endometrial cancer.
- Low parity or nulliparity. Endometrial cancer is more common in women who have borne few (low parity) or no (nulliparity) children. The high levels of progesterone produced during pregnancy have a protective effect against endometrial cancer. The results of one study suggest that nulliparity is associated with a lower survival rate.
- Infertility. Risk is increased due to nulliparity or the use of fertility drugs.
- Polycystic ovary syndrome (PCOS). The increased level of estrogen associated with this disorder raises the risk of cancers of the breast and endometrium.
- Prior use of radiation therapy to treat other pelvic cancers.

The most common symptom of endometrial cancer is unusual vaginal spotting, bleeding, or discharge.

In women who are near **menopause** (perimenopausal), symptoms of endometrial cancer may include bleeding between periods (intermenstrual bleeding), heavy bleeding that lasts for more than seven days, or short menstrual cycles (shorter than 21 days). For women who have gone through menopause, any vaginal bleeding or abnormal discharge is suspect. **Pain** in the pelvic region, painful urination, pain during intercourse, unexplained weight loss, and the presence of a lump (mass) in the pelvis are symptoms that occur late in the disease.

Diagnosis

As of 2014, there were no screening tests that could be used to screen asymptomatic women at average risk of endometrial cancer. If endometrial cancer is suspected, a series of tests are conducted to confirm the diagnosis. The first step involves taking a complete personal and family medical history. A **physical examination**, which includes a thorough pelvic examination, is also performed. The doctor takes a Pap smear to see whether any cancer cells may have spread to the cervix (the lower portion of the uterus).

The doctor may order an **endometrial biopsy**. This is generally performed in the doctor's office and does not require **anesthesia**. A thin flexible tube is inserted through the cervix into the uterus. A small piece of endometrial tissue is removed. The patient may experience some discomfort, which can be minimized by taking an anti-inflammatory medication (such as Advil or Motrin) an hour before the procedure. Women diagnosed with HNPCC or who carry one of the genes associated with this syndrome should begin having endometrial biopsies at age 35.

If an adequate amount of tissue was not obtained by the endometrial biopsy or if the biopsy tissue looks abnormal but confirmation is needed, the doctor may perform a **dilatation and curettage** (D & C). This procedure is done in the outpatient surgery department of a hospital and takes about an hour. The patient may be given general anesthesia. The doctor dilates the cervix and uses a special instrument to scrape tissue from inside the uterus.

The tissue that is obtained from the biopsy or the D & C is sent to a laboratory for examination. If cancer is found, then the type of cancer is determined. The treatment and prognosis depends on the type and stage of the cancer.

Transvaginal ultrasound may be used to measure the thickness of the endometrium. For this painless procedure, a wand-like **ultrasound** transducer is inserted into the vagina to enable visualization and measurement of the uterus, the thickness of the uterine lining, and other pelvic organs.

Other possible diagnostic procedures include sonohysterography and **hysteroscopy**. For sonohysteroscopy, a small tube is passed through the cervix and into the uterus. A small amount of a salt water (saline) solution is injected through the tube to open the space within the uterus and allow ultrasound visualization of the endometrium. For hysteroscopy, a wand-like camera is passed through the cervix to allow direct visualization of the endometrium. Both of these procedures cause discomfort, which may be reduced by taking an anti-inflammatory medication prior to the procedure.

Additional tests may be performed if the doctor suspects that the cancer has spread to the urinary bladder or the bowel. A **cystoscopy** may be done to check the bladder. In a cystoscopy, a lighted tube with a lens is inserted through the urethra (the urinary passage from the bladder to the exterior) and into the bladder to examine these organs for cancerous cells. A procedure called proctoscopy or **sigmoidoscopy** is similar to cystoscopy. It is used to determine whether the cancer has spread to the rectum or lower large intestine.

The doctor may also order such imaging tests as CT scans, **magnetic resonance imaging** (MRI), or **positron emission tomography** (PET scan). These tests are more likely to be used with advanced-stage endometrial cancer. A **chest x ray** may be ordered to see whether an advanced-stage cancer has spread to the lungs.

Treatment

Treatment team

Pap smears usually are performed by a woman's health specialist, a nurse practitioner, a family practice physician, or a gynecologist. These practitioners may also treat precancerous conditions. Procedures for diagnosing endometrial cancer are performed by a gynecologist. A pathologist examines the biopsied tissue for cancer cells. Following diagnosis, a specialist in cancers of the female reproductive system, known as a gynecological oncologist, as well as a radiation oncologist and a surgeon, may join the team. The team may also include a dietitian and a social worker.

Clinical staging

The International Federation of Gynecology and Obstetrics (FIGO) has adopted a staging system for endometrial cancer, as has the American Joint Committee on Cancer (AJCC). The stage of cancer

WWW.BOOKBAZ.IR

is determined after surgery. Endometrial cancer is categorized into five stages (0, I, II, III, and IV); these stages are subdivided (A, B, and possibly C) based on the depth or spread of cancerous tissue. Seventy percent of all uterine cancers are stage I, 10–15% are stage II, and the remainder are stages III and IV. The cancer is also graded (G1, G2, and G3) based upon microscopic analysis of the aggressiveness of the cancer cells.

The AJCC and FIGO stages for endometrial cancer are:

- Stage 0 (used only by the AJCC; this stage is not used in the FIGO staging system). The cancer is limited to the uppermost layer of cells of the endometrium and has not grown into the deeper layers. This stage is also known as carcinoma in situ.
- Stage I. The cancer is limited to the uterus; it has not grown into the cervix or spread to lymph nodes or distant sites.
- Stage II. The cancer involves the uterus and cervix but has not spread to lymph nodes or distant sites.
- Stage III. The cancer has spread beyond the uterus into the vagina, ovaries, or fallopian tubes but is restricted to the pelvic region. It has not spread to lymph nodes or distant sites.
- Stage IV. The cancer has spread to the bladder, bowel, lymph nodes, or such other distant locations as the bones and lungs.

The mainstay of treatment for most stages of endometrial cancer is surgery. **Radiation therapy**, hormonal therapy, and **chemotherapy** are additional treatments (called adjuvant therapy). The necessity of adjuvant therapy is a controversial topic that should be discussed with the patient's treatment team.

Surgery

Most women with endometrial cancer, except those with stage IV disease, are treated with a **hysterectomy**. A simple hysterectomy involves the removal of the uterus. In a bilateral **salpingo-oophorectomy** with total hysterectomy, the ovaries, fallopian tubes, and uterus are removed. This removal may be necessary because endometrial cancer often spreads to the ovaries first. The lymph nodes in the pelvic region may also be biopsied or removed to check for metastasis. A hysterectomy is traditionally performed through an incision in the abdomen (laparotomy); however, endoscopic surgery (**laparoscopy**) with vaginal hysterectomy is also used. Women with stage I disease may require no further treatment. Those with higher grade disease receive adjuvant therapy.

In advanced cases in which the cancer has spread into the abdomen, the surgeon may try to remove as much of the tumor as possible. This procedure is called debulking. It may be done to improve the effectiveness of radiation therapy or chemotherapy.

Radiation therapy

The decision to use radiation therapy depends on the stage of the disease. Radiation therapy may be used before surgery (preoperatively) and/or after surgery (postoperatively). Radiation given from a machine that is outside the body is called external radiation therapy. Sometimes applicators containing radioactive compounds are placed inside the vagina or uterus. This is called internal radiation therapy or brachytherapy and requires hospitalization.

Side effects are common with radiation therapy. The skin in the treated area may become red and dry. **Fatigue**, upset stomach, **diarrhea**, and nausea are also common complaints. Radiation therapy in the pelvic area may cause the vagina to become narrow (vaginal stenosis), making intercourse painful. **Premature menopause** and some problems with urination may also occur.

Chemotherapy

Chemotherapy is usually reserved for women with stage IV or recurrent disease because this therapy is not a very effective treatment for endometrial cancer. The **anticancer drugs** are given by mouth or intravenously. The drugs most commonly used to treat endometrial cancer are cisplatin, paclitaxel, doxorubicin, and carboplatin; they may be given singly or in combination. Side effects of chemotherapy include stomach upset, **vomiting**, appetite loss, hair loss, mouth or vaginal sores, fatigue, menstrual cycle changes, and premature menopause. There is also an increased chance of infections.

Hormone therapy

Hormone therapy for endometrial cancer should not be confused with **hormone replacement therapy** for menopause. Hormone therapy for cancer uses progesterone-like drugs called progestins to slow the growth of endometrial cells. These drugs are usually available as pills; the two compounds most commonly used are medroxyprogesterone acetate and megestrol acetate. This therapy is usually reserved for women with advanced or recurrent disease. Side effects include fatigue, fluid retention, and appetite and weight changes. Other types of hormonal therapies that may

be used to treat endometrial cancer in women whose ovaries have been removed include the aromatase inhibitors, which lower estrogen levels in the body. These drugs include letrozole, anastrozole, and exemestane. Women whose ovaries have not been removed may be treated with drugs that oppose the action of gonadotropin-releasing hormone (GNRH). GNRH agonists include leuprolide and goserelin.

Alternatives

Although alternative and complementary therapies are used by many cancer patients, very few controlled studies on the effectiveness of such therapies exist. Mind-body techniques, such as prayer, **biofeedback**, visualization, **meditation**, and **yoga**, have not shown any effect in reducing cancer, but they can reduce **stress** and lessen some of the side effects of cancer treatments.

Prognosis

Because it is possible to detect endometrial cancer early, the chances of curing it are excellent. The overall 5-year survival rate for endometrial cancer (accounting for all stages of this disease) is about 79%. The 5-year survival rates for endometrial cancer by stage are: 90%, stage 0; 85%, stage I; 69%, stage II; 50%, stage III; and 17%, stage IV. Endometrial cancer most often spreads to the lungs, liver, bones, brain, vagina, and certain lymph nodes.

Clinical trials

As of 2014, there were 104 open studies for endometrial cancer within the United States. These included the testing of different combinations of chemotherapy drugs, new methods of cancer imaging, the potential benefits of fertility-sparing surgery versus complete removal of the ovaries, and new drugs for the treatment of advanced-stage endometrial cancer.

Prevention

Women (especially postmenopausal women) should report any abnormal vaginal bleeding or discharge to their doctor. Controlling **obesity**, high blood pressure, and diabetes can help to reduce the risk of this disease. Women on estrogen replacement therapy have a substantially reduced risk of endometrial cancer if progestins are taken simultaneously. The long-term use of birth control pills has been shown to reduce the risk of this cancer. Women who have irregular periods may be prescribed birth control pills to help prevent endometrial cancer. Women who are taking tamoxifen and those who carry the HNPCC gene should be screened regularly and receive annual pelvic examinations. A hysterectomy is often recommended as a preventive treatment for women diagnosed with HNPCC.

REVISED BY REBECCA J. FREY, PhD

Endometriosis

Definition

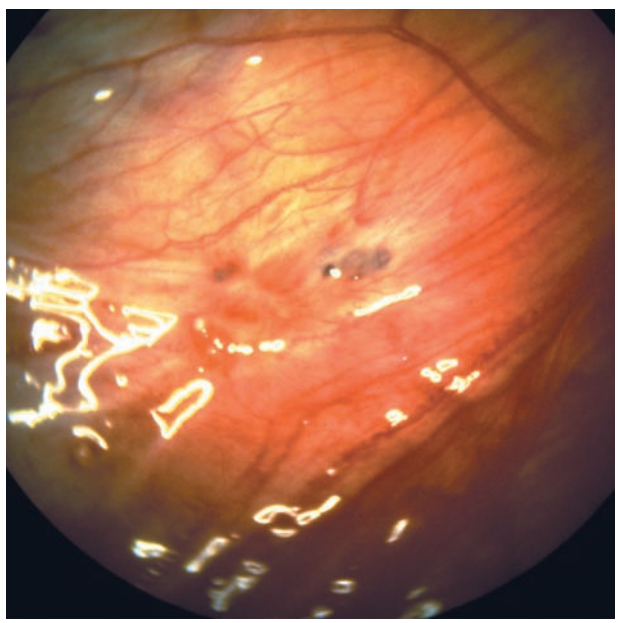
Endometriosis is a condition in which bits of the tissue similar to the tissue lining the uterus (endometrium) grow in other parts of the body

Demographics

It is difficult to determine the exact number of women who have endometriosis because some never show symptoms, but estimates suggest that 6–8% of women of childbearing age in the United States have the condition. It most commonly is diagnosed in women between the ages of 25 and 40. Endometriosis can appear in the teenage girls, but rarely before the start of menstruation. It is seldom seen in postmenopausal women and occurs independent of race or ethnicity. The prevalence of endometriosis in the United States has remained stable since the early 1980s.

Description

Endometrial tissue like that lining the uterus sometimes develops in other parts of the body. These patches of misplaced endometrial tissue are called implants. Like the endometrial lining the uterus, this tissue builds up and sheds in response to monthly



An endoscopic view of endometriosis on pelvic wall. *(Custom Medical Stock Photo, Inc.)*

hormonal cycles (menstruation). However, there is no natural outlet for the material from these implants. Instead, it moves onto surrounding tissues, causing swelling, inflammation, and often **pain**. Repeated irritation leads to the development of scar tissue and **adhesions** in the area of the endometrial implants. Depending on their location, these **scars** may interfere with a woman's ability to conceive a child.

Endometrial implants are found most often on the pelvic organs—the ovaries, Fallopian tubes, and in the cavity behind the uterus. They can also be found on organs in the abdominal cavity such as the bladder and large intestine (colon). Occasionally, this tissue grows in distant parts of the body such as the lungs, arms, and kidneys.

Endometriosis is a progressive condition that usually advances slowly, over the course of many years. Doctors rank cases from minimal to severe based on factors such as the number and size of the endometrial implants, their appearance and location, and the extent of the scar tissue and adhesions in the vicinity of the growths.

Risk factors

If a first-degree female relative (mother, sister) has endometriosis, a woman has a higher risk of also developing the disorder. Another possible risk factor is the length of a woman's menstrual cycle. Women whose periods last longer than a week with an interval of less than 27 days between them seem to be more prone to the condition. This corresponds with studies that show that women with the most stable hormone levels are less likely to develop endometriosis. In addition, some studies have found that women who are tall and thin with a lower than average **body mass index** (BMI) are more likely to develop endometriosis, although there is no understanding of why this occurs.

Causes and symptoms

Endometriosis was once called the "career woman's disease" because it was thought to be a product of delayed childbearing. The statistics defy such a narrow generalization; however, the hormonal changes that accompany **pregnancy** may slow the progress of the condition.

Although the exact cause of endometriosis is unknown, several theories have been put forward to explain the origins of the disorder. These include:

- Retrograde (reverse) menstruation theory. Originally proposed in the 1920s, this theory states that a partial reversal in the direction of menstrual flow (a common event) sends discarded endometrial cells into the Fallopian tubes and then into the body cavity where they attach to internal organs and seed endometrial implants. There is considerable evidence to support this explanation. Reversed menstrual flow occurs in 70–90% of women and is thought to be more common in women with endometriosis. However, this does not explain why many women with retrograde menstrual flow do not develop endometriosis.
- Vascular-lymphatic theory. This theory suggests that the lymph system or blood vessels (vascular system) is the vehicle for the distribution of endometrial cells out of the uterus.
- Coelomic metaplasia theory. The endometrium and the peritoneal mesothelium arise from the same embryonic cells called coelomic wall epithelium. According to this hypothesis, some cells in the peritoneal mesothelium retain their embryonic ability to transform into endometrium, either spontaneously or after chronic irritation caused by exposure to retrograde menstrual flow.
- Iatrogenic theory. Iatrogenic disorders are those caused by the action of a physician. This theory suggests that surgery or procedures in the region of the woman's reproductive organs either deposits endometrial cells in inappropriate places where they grow or in some stimulates other cells to develop into endometrium.

In addition to these theories, the following factors are thought to influence the development of endometriosis:

- Heredity. A woman's chance of developing endometriosis is seven times greater if her mother or sisters have the disease.
- Immune system function. Women with endometriosis may have lower functioning immune systems that have trouble eliminating stray endometrial cells. This would explain why a high percentage of women experience reversed menstrual flow while relatively few develop endometriosis.
- Dioxin exposure. Some research suggests a link between the exposure to dioxin (TCCD), a toxic chemical found in weed killers, and the development of endometriosis.

While many women with endometriosis suffer debilitating chronic or acute pain symptom, others have none and are unaware they have the disorder. There does not seem to be any relation between the severity of the symptoms and the extent of the disorder.

WWW.BOOKBAZ.IR

The most common symptoms of endometriosis are:

- Menstrual pain (dysmenorrhea). Pain in the lower abdomen that begins a day or two before the menstrual period starts and continues through to the end is typical of endometriosis. Some women also report lower back aches and pain during urination and bowel movement, especially during their periods.
- Painful sexual intercourse. Pressure on the vagina and cervix causes severe pain for some women.
- Abnormal bleeding. Heavy menstrual periods, irregular bleeding, and spotting are common features of endometriosis.
- Infertility. There is a strong association between endometriosis and infertility, although the reasons for this have not been fully explained. It is thought that the build up of scar tissue and adhesions blocks the Fallopian tubes and prevents the ovaries from releasing eggs. Endometriosis may also affect fertility by causing hormonal irregularities and a higher rate of early miscarriage.

Diagnosis

If a doctor suspects endometriosis, the first step will be to perform a **pelvic exam** to try to feel if implants are present. Very often there is no strong evidence of endometriosis from a physical exam.

Tests

The only way to make a definitive diagnosis is through minor surgery called a **laparoscopy**. A laparoscope, a slender scope with a light on the end, is inserted into the woman's abdomen through a small incision near her belly button. This allows the doctor to examine the internal organs for endometriotic growths. Often, a sample of tissue (biopsy) is taken for later examination in the laboratory. Endometriosis is sometimes unintentionally discovered when a woman has abdominal surgery for another reason such as **tubal ligation** or **hysterectomy**.

Various imaging techniques such as transvaginal ultrasonography or endorectal ultrasonography, computed tomography scan (CT scan), **magnetic resonance imaging** (MRI) can offer some additional information but are not useful in making the initial diagnosis. They may be done, however, to rule out other conditions with similar symptoms. Various other tests such as a pregnancy test, may also be done to rule out other conditions. A test for the blood protein CA125 is not useful in making the initial diagnosis, but testing for this substance before and after treatment can predict a recurrence of the disease.

KEY TERMS

Adhesions—Web-like scar tissue that may develop as a result of surgery or a disease such as endometriosis and bind organs to one another.

Endometrial implants—Growths of endometrial tissue that attach to organs, primarily in the pelvic cavity.

Endometrium—The tissue lining the uterus that grows and sheds each month during a woman's menstrual cycle.

Estrogen—Any of several steroid hormones, produced mainly in the ovaries, that stimulate the development of the endometrium and the development of female secondary sexual characteristics.

Hormonal therapy—Use of hormone medications to inhibit menstruation and relieve the symptoms of endometriosis.

Iatrogenic—Resulting from the activity of the physician.

Laparoscopy—A diagnostic procedure, which when performed for endometriosis performed by inserting a slender, wand-like instrument through a small incision in the woman's abdomen.

Menopause—The end of a woman's menstrual periods when a woman no longer can conceive a child.

Retrograde menstruation—Menstrual flow that travels into the body cavity rather than being expelled through the uterus.

Treatment

How endometriosis is treated depends on the woman's symptoms, her age, the extent of the disease, and her personal preferences. The condition cannot be fully eradicated without surgery. Conservative treatment focuses on managing the pain, preserving fertility, and delaying the progress of the condition.

Drugs

Over-the-counter pain relievers such as **aspirin** and **acetaminophen** (Tylenol) are useful for mild cramping and menstrual pain.)ver-the-counter or prescription-strength **nonsteroidal anti-inflammatory drugs** (NSAIDs), such as ibuprofen (Motrin, Advil) and naproxen (Aleve, Naprosyn), may be effective. If pain is severe, a doctor may prescribe narcotic pain

medications, although these can be addicting and are rarely used.

Hormonal therapies may effectively treat symptoms of endometriosis, but they also act as contraceptives. Before beginning hormone treatment, a woman should discuss her reproductive plans with her physician.

The following hormonal treatments may be used to treat endometriosis:

- Oral contraceptives. Continuously taking estrogen-progestin pills tricks the body into thinking it is pregnant. This state of pseudo pregnancy may result in pelvic pain and a temporary withering of endometrial implants.
- Danazol (Danocrine) and gestrinone are synthetic male hormones that lower estrogen levels, prevent menstruation, and shrink endometrial tissues. Negative side effects include weight gain and menopause-like symptoms and cause some women to develop masculine characteristics.
- Progestins. Medroxyprogesterone (Depo-Provera) and related drugs also may be used in treating endometriosis. They have been proven effective in minimizing pain and halting the progress of the condition but are rarely used because of the high rate of side effects.
- Gonadotropin-releasing hormone (GnHR) agonists. These estrogen-inhibiting drugs successfully limit pain and prevent the growth of endometrial implants. They can cause menopause symptoms, however, and doses have to be closely regulated to prevent bone loss associated with low estrogen levels.

Surgery

Removing the uterus, ovaries, and Fallopian tubes is the only permanent method of eliminating endometriosis. This is an extreme measure that deprives a woman of her ability to bear children and forces her body into early **menopause**. In some cases, endometrial implants can be removed with **laser surgery** performed through a laparoscope. For women with minimal endometriosis, this technique usually is successful in reducing pain and slowing the condition's progress. It may help infertile women increase their chances of becoming pregnant.

Alternatives

Although severe endometriosis should not be self-treated, many women find they can help relieve symptoms through alternative therapies. In a survey conducted by the Endometriosis Association, 40–60% of the women who used alternative medicines reported relief of pain and other symptoms.

DIET. A high-fiber diet, particularly from grains and beans, may decrease cramping and inflammation. The oils in seeds, nuts, and certain fish (cod, salmon, mackerel, and sardines) may help to relieve cramping. Carrots, beets, lemons, cauliflower, Brussels sprouts, cabbage, onions, garlic, citrus fruits, vegetables, chicory, radicchio, and yogurt may help to reduce symptoms. Sugar and animal fats can increase inflammation and aggravate pain. Milk and meat may contain hormones, so these should be avoided. Vegetarian or vegan **diets** may be recommended for those with endometriosis. Occasionally, an allergy elimination diet may be recommended.

SUPPLEMENTS. The following supplements can be used to treat endometriosis:

- vitamin B complex to help the liver break down excess estrogen
- vitamin C to reduce heavy menstrual bleeding
- calcium
- bioflavonoids to help reduce heavy menstrual bleeding
- magnesium to relieve pain and flush out toxins
- vitamin E to heal inflamed tissues
- iron for anemia resulting from heavy bleeding
- lipotropic factors (Choline, methionine, and inositol enhance liver function)
- fish oil capsules, flax oil, or any essential fatty acid to reduce cramping

HERBAL REMEDIES. Several herbal remedies for endometriosis exist. The first four in this list are the most commonly used remedies:

- Genistein (soy/isoflavone) helps the body excrete excess estrogen and possibly blocks estrogen's effect.
- Cramp bark (Viburnum opulus) helps ease cramping
- Dong quai (Angelica sinensis) balances hormone levels and reduces inflammation.
- Black cohosh (Cimicifuga racemosa) helps the body excrete excess estrogen and improves the health of pelvic organs.
- Red clover (Trifolium pratense) balances hormone levels.
- Milk thistle (Silybum marianum) may improve liver function.
- Life root (Senecio aureus) may improve the health of pelvic organs
- Feverfew (Chrysanthemum parthenium) eases pain and cramping.

WWW.BOOKBAZ.IR

- Dandelion eases pain and cramping and supports the liver.
- Yarrow (Archillea millefolium) eases cramping and restores hormonal balance.
- Evening primrose (Oenothera biennis) oil relieved endometriosis symptoms in 90% of patients in one study.
- Shepherd's purse (Capsella bursa-pastoris) reduces heavy menstrual bleeding and tones the uterus.
- Meadowsweet (Filipendula ulmaria) reduces pain.

OTHER THERAPIES. Other remedies for endometriosis include **acupuncture** or **acupressure** to relieve pain, visualization, **guided imagery**, naturopathy, homeopathy (Lilium tigrum, sepia, and belladonna), **hydrotherapy**, **exercise**, and **meditation**.

Home remedies

Studies have shown that by gradually increasing their level of physical activity some women are able to reduce their level of pelvic pain. However, for unknown reasons, this does not work for all women.

Prognosis

Most women who have endometriosis have minimal symptoms and do well with conservative treatment. Overall, endometriosis symptoms recur in an average of 40% of women over the five years following treatment. With hormonal therapy, pain returned after five years in 37% of patients with minimal symptoms and 74% of those with severe cases. The highest success rate followed complete removal of implants using laser surgery. Eighty percent of these women were still pain-free five years later. In cases that do not respond to these treatments, a woman and her doctor may consider surgery to remove her reproductive organs. The most serious complication from endometriosis is reduced fertility or complete **infertility**.

Prevention

There is no proven way to prevent endometriosis.

Endorectal ultrasound

Definition

Endorectal **ultrasound** (ERUS) is a procedure where a probe is inserted into the rectum and high frequency sound waves (ultrasound waves) are generated. The pattern of echoes as they bounce off tissues is converted into a picture (sonogram) on a television screen.

Purpose

ERUS is used as a diagnostic procedure in **rectal cancer** to determine stage of the tumor and as a post-radiation, presurgical examination to assess extent of tumor shrinkage. ERUS can also be used in cases of anal **fistula** (an abnormal passage) and problems with the anal sphincter muscles (muscles that control the opening and closing of the anus).

Precautions

Normal precautions should be taken with any diagnostic procedure. Since the population in which this procedure is normally done is elderly, the imaging staff should be extra cautious about stressing the

patient. The procedure is invasive and may be embarrassing to some. Other patients may be anxious about their medical condition since endorectal ultrasounds are not routine. This places an added burden on already stressed hearts and nervous systems. Physicians, nurses, and technicians may need to be prepared for **stress** reactions that could include the heart, **asthma**, or anxious behaviors.

Description

ERUS has been used as a means to determine the depth of rectal cancers and to assess whether the tumor has affected surrounding tissues. This pretreatment procedure has proven to be an accurate tool for tailoring surgery for patients.

Problems with interpretation of the sonograms after radiation and before surgery have resulted in tumors being identified that were merely the formation of fibrous tissues that remained after the tumors had been eliminated by the radiation. Yet, some of the fibrous areas actually hid residual tumors. Rectal anatomy itself can affect the accuracy of ultrasound reading. This makes ERUS problematic in determining the amount of tumor reduction a patient has after **radiation therapy**.

Preparation

The patient must evacuate the bowels completely before the procedure is done. This usually is assisted though the use of several **enemas**. The patient may be told to adhere to a liquid diet the day prior to doing this procedure. The probe is inserted, usually with little discomfort for the patient since it will only be examining the first few inches of the colon.

Aftercare

Since ERUS is a minor invasive procedure, there is no aftercare.

Risks

There are no risks to having an ultrasound.

Results

Normal results after an endorectal ultrasound are normal, healthy tissues.

Abnormal results

Abnormal results range from any number of congenital deformities in the lining of the rectum to serious rectal cancers.

KEY TERMS

Anal sphincter muscles—Muscles that control the opening and closing of the anus.

Fistula—An abnormal passage.

Sonogram—The picture formed by the pattern of echoes from an ultra sound.

Ultrasound waves—High-frequency sound waves.

Endoscopic retrograde cholangiopancreatography

Definition

Endoscopic retrograde cholangiopancreatography (ERCP) is an imaging technique used to diagnose diseases of the pancreas, liver, gallbladder, and bile ducts. It combines **endoscopy** and x-ray imaging.

Purpose

ERCP is used in the management of diseases that affect the gastrointestinal tract, specifically the pancreas, liver, gall bladder, and bile ducts. The pancreas is an organ that secretes pancreatic juice into the upper part of the intestine. Pancreatic juice is composed of specialized proteins that help to digest fats, proteins, and carbohydrates. Bile is a substance that helps to digest fats; it is produced by the liver, secreted through the bile ducts, and stored in the gallbladder. Bile is released into the small intestine after a person has eaten a meal containing fat.

WWW.BOOKBAZ.IR

A doctor may recommend ERCP if a patient is experiencing abdominal **pain** of unknown origin, weight loss, or **jaundice**. These may be symptoms of biliary disease. For instance, **gallstones** that form in the gallbladder or bile ducts may become stuck there, causing cramping or dull pain in the upper right area of the abdomen, **fever**, and/or jaundice. Other causes of biliary obstruction include tumors, injury from gallbladder surgery, or inflammation. The bile ducts may also become narrowed (called a biliary stricture) as a result of cancer, blunt **trauma** to the abdomen, **pancreatitis** (inflammation of the pancreas), or **primary biliary cirrhosis** (PBC). PBC may be caused by a condition called primary sclerosing **cholangitis**, an inflammation of the bile ducts that may cause pain, jaundice, **itching**, or other symptoms. These symptoms may also be experienced by a patient with cholangitis, or with infection of the bile ducts caused by bacteria or parasites.

ERCP can also be used to diagnose a number of pancreatic disorders. Pancreatitis is an inflammation of the pancreas, caused by chronic alcohol abuse, injury, obstruction of the pancreatic ducts (e.g., by gallstones), or other factors. The condition may be either acute (having a severe but short course) or chronic (persistent). Symptoms of pancreatitis include abdominal pain, weight loss, nausea, and **vomiting**. ERCP may be used to diagnose cancer of the pancreas; pancreatic pseudocysts (collections of pancreatic fluid); or strictures of the pancreatic ducts. Certain congenital disorders may also be identified by ERCP, such as pancreas divisum, a condition in which parts of the pancreas fail to fuse during fetal development.

KEY TERMS

Bile—A bitter yellowish-brown fluid secreted by the liver that contains bile salts, bile pigments, cholesterol, and other substances. It helps the body to digest and absorb fats.

Congenital—Present at birth.

Endoscope—An instrument with a light source attached that allows the doctor to examine the inside of the digestive tract or other hollow organ.

Gastrointestinal tract—A group of organs and related structures that includes the esophagus, stomach, liver, gallbladder, pancreas, small intestine, large intestine, rectum, and anus.

Jaundice—A condition characterized by deposits of bile pigments in the skin, mucous membranes, and the whites of the eyes. It is also known as icterus.

Magnetic resonance imaging—A technique that uses a strong magnetic field and pulses of radio waves to produce cross-sectional images of the body.

Stent—A thin rod-like or tube-like device made of wire mesh, inserted into a blood vessel or duct to keep it open.

Stricture—An abnormal narrowing of a duct or canal.

Demographics

Diseases of the pancreas and biliary tract affect millions of Americans each year. According to the National Health and Nutrition Survey, gallbladder disease affects approximately 6.3 million men and 14.2 million women in the United States between the ages of 24 and 74. Approximately one million new cases of gallstones are diagnosed each year. The incidence of gallstones is higher among women; adults over the age of 40; and people who are overweight. Primary sclerosing cholangitis occurs at a rate of two to seven cases per 100,000 persons. The rate of gallbladder cancer is approximately 2.5 out of 100,000 persons. In addition, approximately 87,000 cases of pancreatitis and 30,000 cases of pancreatic cancer are diagnosed each year in the United States.

Description

ERCP is performed with the patient given either a sedative or general **anesthesia**. The physician then sprays the back of the patient's throat with a local anesthetic. The endoscope (a thin, hollow tube attached to a viewing screen) is then inserted into the mouth. It is threaded down the esophagus, through the stomach, and into the duodenum (upper part of the small intestine) until it reaches the spot where the bile and pancreatic ducts empty into the duodenum. At this point a small tube called a cannula is inserted through the endoscope and used to inject a contrast dye into the ducts. The term "retrograde" in the name of the procedure refers to the backward direction of the dye as it is injected through the ducts. A series of x rays are then taken as the dye moves through the ducts.

If the x rays show that a problem exists, ERCP may be used as a therapeutic tool. Special instruments can be inserted into the endoscope to remove gallstones, take samples of tissue for further examination (e.g., in the case of suspected cancer), or place a special tube called a stent into a duct to relieve an obstruction.

Diagnosis/Preparation

ERCP is generally not performed unless other less invasive diagnostic tests have first been used to determine the cause of a patient's symptoms. Such tests include:

- complete medical history and physical examination
- blood tests (certain diseases can be diagnosed by abnormal levels of blood components)
- ultrasound imaging (a procedure that uses high-frequency sound waves to visualize structures in the human body)
- computed tomography (CT) scan (an imaging device that uses x rays to produce two-dimensional cross-sections on a viewing screen)

Before undergoing ERCP, the patient will be instructed to refrain from eating or drinking for at least six hours to ensure that the stomach and upper part of the intestine are empty. Arrangements should be made for someone to take the patient home after the procedure, as he or she will not be able to drive. The physician should also be given a complete list of all prescription, over-the-counter, and alternative medications or preparations that the patient is taking. The patient should also notify the doctor if he or she is allergic to iodine because the contrast dye contains it.

Aftercare

After the procedure, the patient will remain at the hospital or outpatient facility until the effects of the sedative wear off and no signs of any complications have appeared. A longer stay may be warranted if the patient experiences complications or if other procedures were performed.

Risks

Complications that have been reported with ERCP include pancreatitis; cholangitis (inflammation of the bile ducts); **cholecystitis** (inflammation of the gallbladder); injury to the duodenum; pain; bleeding; infection; and formation of **blood clots**. Factors that increase the risk of complications include liver damage, bleeding disorders, a history of post-ERCP complications, and a less experienced endoscopist.

The overall complication rate associated with ERCP is approximately 11%. Pancreatitis may occur in up to 7% of patients. Cholangitis and cholecystitis occur in less than 1% of patients. Infection, injury, bleeding, and blot clot formation also occur in less than 1%. The mortality rate for ERCP is approximately 0.1%.

Results

Following ERCP, the patient's biliary and pancreatic ducts should be free of stones and show no strictures, obstructions, or evidence of infection or inflammation.

Alternatives

Although less invasive techniques exist (such as computed tomography and ultrasonography) to help to diagnose gastrointestinal diseases, these imaging studies are often not precise enough to allow for definite diagnosis of certain conditions. **Percutaneous transhepatic cholangiography** (PTCA) is an alternative to ERCP that involves the insertion of a long, flexible needle through the skin to the bile ducts; contrast dye is then injected into the ducts so that they may be visualized by x ray. PTCA may be recommended if ERCP fails or cannot be performed. Magnetic resonance cholangiopancreatography (MRCP) is an imaging technology that allows for noninvasive examination of the biliary and pancreatic ducts. Its disadvantage, however, is that unlike ERCP, it cannot be used for therapeutic procedures as well as imaging.

Endoscopic sphincterotomy

Definition

Endoscopic sphincterotomy or endoscopic retrograde sphincterotomy (ERS) is a relatively new endoscopic technique developed to examine and treat abnormalities of the bile ducts, pancreas and gallbladder. The procedure was developed as an extension to the diagnostic examination, ERCP (**endoscopic retrograde cholangiopancreatography**); with the addition of "sphincterotomy," abnormalities found during the study could be treated at the same time without the need for invasive surgery.

The term ERS has three parts to its definition;

- endoscopic refers to the use of an endoscope
- retrograde refers to the insertion of the endoscope *up* into the ducts in a direction opposite to or against the normal flow of bile *down* the ducts
- sphincterotomy, which means cutting of the sphincter or muscle that lies at the juncture of the intestine with both the bile and pancreatic ducts

Purpose

Until the 1970s, patients with symptoms related to disease of the bile ducts or pancreas frequently needed surgery to diagnose the cause and treat any abnormalities. ERCP allowed physicians for the first time to obtain high quality x rays of the common bile and pancreatic ducts, and detect areas of narrowing (strictures), stones, and tumors. ERCP was not initially designed for treatment. ERS was developed shortly after and enabled physicians to treat the abnormalities identified by the injection of dye and x rays.

The revolutionary technique made possible the endoscopic removal of stones and stretching of areas of narrowing (strictures). It has since been expanded to include drainage of bile from blocked ducts and treatment of various abnormalities of the pancreas.

Precautions

The most important precaution related to both ERCP and ERS is to have the procedure performed by an experienced physician. ERS is technically more difficult than many other gastrointestinal endoscopic studies, including ERCP. Patients should inquire as to the physician's experience with the procedure. The physician should also be informed of any **allergies**, medication use, and medical problems.

KEY TERMS

Endoscope, Endoscopy—An endoscope as used in the field of gastroenterology is a thin flexible tube which uses a lens or miniature camera to view various areas of the gastrointestinal tract. When the procedure is performed to examine certain organs such as the bile ducts or pancreas, the organs are not viewed directly, but rather indirectly through the injection of x-ray dye. The performance of an exam using an endoscope is referred by the general term endoscopy. Diagnosis through biopsies or other means and therapeutic procedures can be done with these instruments.

NSAIDS—This abbreviation stands for non-steroidal anti-inflammatory drugs, which are medications such as Ibufprofen that are used to control pain and inflammation. Most may be purchased over the counter. One of their major side effects is that they decrease the effect of the normal blood clotting factors in blood. In patients undergoing surgical or endoscopic procedures, this can lead to an increased risk of bleeding.

Description

ERS is generally performed only after ERCP has been successfully accomplished and detail of the anatomy and abnormalities is known. During ERS, a number of various instruments are inserted through the endoscope in order to "cut" or stretch the sphincter. Once this is done, additional instruments are passed that enable the removal of stones and the stretching of narrowed regions of the ducts. Drains (stents) can also be used to prevent a narrowed area from rapidly returning to its previously narrowed state.

Preparation

The upper intestinal tract must be empty for the procedure, so patients must not eat or drink for at least six to 12 hours before the exam. Patients need to inquire about taking their medications before the procedure. Some patients may require **antibiotics** before and/or after the procedure. When possible, **aspirin** or NSAIDS should not be taken within several days before the procedure, because they interfere with blood clotting.

Aftercare

When ERS is performed, physicians will usually want to observe the patient closely for several hours to

ensure that there are no signs of complications. **Pain** or any other unusual symptoms should be reported. **Admission to the hospital** may be advised.

Risks

ERS complications are related either to the drugs used during the procedure, or the results of dye injection or cutting of tissue. The overall complication rate is 5–10%. During the exam, the endoscopist can cut or stretch structures (such as the muscle leading to the bile duct) to treat the cause of the patient's symptoms. Cutting or stretching of these structures can sometimes cause a hole or perforation. The use of sedatives also carries a risk of decreasing cardiac and respiratory function, however, it is very difficult to perform these procedures without these drugs.

Other major complications related to ERCP or ERS are **pancreatitis** (inflammation of the pancreas) and **cholangitis** (inflammation of the bile ducts). **Bacteremia** (the passage of bacteria into the bloodstream) and bleeding are also risks.

Results

Certain standards have been set for the diameter or width of the pancreatic and bile ducts. Measurements by x ray are used to determine if the ducts are too large (dilated) or too narrow (strictured). Lastly, the ducts and gallbladder should be free of any solid particles, such as stones, and free of areas of narrowing.

David Kaminstein, MD

Endoscopic ultrasound

Definition

Endoscopic **ultrasound** (EUS) is an imaging test that combines an endoscopic examination with an ultrasound examination. A very thin flexible tube is passed through the mouth, into the throat, and then through either the bronchi into the lungs or through the esophagus into the stomach. Alternatively, the tube can be passed through the anus and into the lower gastrointestinal tract. A tiny ultrasound transducer is built into this tube, allowing close examination of areas in either the upper or lower gastrointestinal tract or the respiratory tract. Endoscopic ultrasound is used to diagnose conditions in these areas of the body, to stage cancer, and to access biopsy samples.

Purpose

Endoscopic ultrasound can be used to evaluate a number of conditions, including:

- cancer of the esophagus, stomach, pancreas, rectum, or lungs
- gallstones in the bile duct
- pancreatitis
- pancreatic cysts
- dysfunctional anal sphincter
- incontinence
- Barrett's esophagus
- rectal fistulas

EUS can also be used in a variety of therapeutic applications, including:

- pancreatic pseudocyst drainage
- treatment of cystic lesions of the pancreas
- EUS-guided cholangiopancreatography
- localized therapy for pancreatic tumors
- treatment of subepithelial lesions and gastric varices

Description

After the patient is adequately sedated, he or she is placed in the appropriate position, depending on the type of examination being performed. For upper gastrointestinal or respiratory exams, the throat is sprayed with a local anesthetic to prevent the gag reflex from interfering with introduction of the endoscope. Air may be introduced into the gastrointestinal tract in order to expand the area for easier visualization of the structures.

The endoscope is passed either through the mouth into the trachea and then through the bronchial tree into the lungs, or through the mouth into the esophagus and then into the stomach. From the stomach, the endoscope can be passed further into the small intestine, where it will be used to access the pancreas. Alternatively, the endoscope can be introduced through the rectum into the large intestine for examination of the bowel.

WWW.BOOKBAZ.IR

The progression of the endoscope past the various structures is visible to the examiner on a television monitor. A separate ultrasound monitor allows the examiner to view ultrasound images during the course of the examination. Fine-needle aspiration can be performed through the endoscope in order to obtain biopsy samples.

Precautions

Patients who are taking blood thinners, **aspirin**, or **nonsteroidal anti-inflammatory drugs** (NSAIDs) may need to discontinue their use in advance of the test to avoid the risk of bleeding.

Preparation

Patients need to stop eating and drinking for at least six hours prior to the exam. For examinations involving the gastrointestinal tract, **enemas** and/or **laxatives** may be used to empty the GI tract of feces. An intravenous line is placed in order to provide the patient with fluids and **sedation** during the exam, and sedation helps make the passage of the **endoscopy** tube less traumatic and more comfortable. A variety of monitors attached to the patient help the physician track the patient's blood pressure, heart rate, and blood oxygen level throughout the procedure.

Aftercare

After the test, patients should rest until the sedative wears off. Once their gag reflex has returned, they can begin drinking fluids, and after some hours can progress to a light diet. Most people resume their normal diet and activity level within 24 hours of this type of test.

Risks

In general, endoscopic ultrasound examinations that are performed without fine-needle aspiration are relatively low risk. Only about 1 in 2,000 patients develop any kind of complication. Possible problems include reaction to the sedatives (such as nausea, **vomiting**, **hives**, or skin rash), or swelling or infection of the area where the intravenous line was placed. The most serious complication involves inadvertent perforation (puncture) of the intestinal wall, requiring surgical repair. This is an extremely rare complication.

There is a slightly higher rate of complication when endoscopic ultrasound is performed in conjunction with fine-needle aspiration. Complication rates for this procedure are about 0.5–1%. In this case, there is some chance of bleeding if the needle accidentally passes through the intestinal wall. This may require that the patient be hospitalized for observation, or, even more rarely, for a blood **transfusion**. Infection can also occur following fine-needle aspiration. When the procedure involves the pancreas, there is a risk of pancreatic inflammation or **pancreatitis**, requiring hospitalization and treatment.

KEY TERMS

Barrett's esophagus—A condition in which the esophageal tissue closest to the stomach contains highly abnormal cells that have a great likelihood of converting to cancer.

Endoscope—A narrow, flexible tube with a fiber optic light on it, used to pass into the body for a variety of medical examinations.

Fine-needle aspiration—Use of a very thin type of needle to withdraw cells from an organ, a tumor, or other body tissue, in order to examine those cells for abnormalities (such as malignancy) in a pathology laboratory.

Fistula—An abnormal opening occurring between two organs or an abnormal opening leading to the outside of the body.

Pancreatitis—Inflammation of the pancreas.

Transducer—The instrument that sends sound waves into organs of the body in order to produce ultrasound images.

Results

Normal results mean that there were no structural abnormalities visualized during the course of the examination.

Abnormal results range from the discovery of tumors, cysts, or **gallstones**, to the identification of cancerous tissue upon examination of biopsy material.

Rosalyn Carson-DeWitt, MD

Endoscopy

Definition

An endoscopy is a procedure that uses a small camera mounted on a thin, flexible tube called an endoscope to allow a doctor to see inside the body.

Purpose

Endoscopy is used to provide the doctor or surgeon with the ability to see inside the patient's body. Unlike many other forms of imaging, such as x ray and **ultrasound**, endoscopy can provide the doctor with a real-time view with true colors. It also is sometimes used to remove polyps, cauterize bleeding, or remove samples for examination under the microscope.

Patient undergoing an endoscopic exam. *(© National Audubon Society Collection/Photo Researchers, Inc.)*

Endoscopy is used in a variety of settings. It is often used to help diagnose the cause of **pain** or other symptoms that are of unclear origin. It can also be used during **minimally invasive surgery**, when an endoscopy is passed through a very small incision so that the surgeon is able to view the inside of the patient and perform the surgery.

Description

A doctor determines the need for an endoscopy based on a **physical examination** of the patient, the patient's self-reported symptoms, a **health history**, and the results of any other diagnostic imaging, blood, or urine tests. The endoscopy may be performed in a doctor's office, in a clinic, or in a hospital. In general, an endoscopy is performed by a doctor who specializes in the area being imaged. For example, an endoscopy of the upper digestive system is performed by a gastroenterologist, a doctor who specializes in the gastrointestinal system. A surgeon may perform an endoscopy if the endoscopy is being used to visualize the surgery site during minimally invasive surgery.

During the procedure, a variety of other health care team members may assist the doctor or surgeon who is performing the endoscopy. Technologists may help to set up and monitor video and other equipment. One or more nurses may supervise the administration of any medications or sedatives, and may help to monitor the patient's vital signs during the procedure. If the patient is going to be under general anesthesia during the procedure, an anesthesiologist will administer the anesthesia and be present during the procedure to monitor the patient. If the endoscopy is being performed doing a surgery a variety of operating room

WWW.BOOKBAZ.IR

KEY TERMS

Biopsy—Removal of a small tissue sample from the body to examine for evidence of disease.

Gastroenterologist—A doctor who specializes in diagnosing and treating conditions of the gastrointestinal system, including the mouth, pharynx, esophagus, diaphragm, stomach, gall bladder, bile duct, liver, small intestine, large intestine, and anus.

Polyp—An abnormal growth of tissue arising from and protruding from a mucous membrane.

nurses, technologists, and technicians may be present to assist. If any material is removed during the procedure for a biopsy, a laboratory technician may examine the sample to determine if it is cancerous.

During endoscopy, a small camera or viewer attached to the end of a thin, usually flexible tube, is passed into the individual. This device is called an endoscope. The endoscope is usually introduced into the patient through the mouth, rectum, ureter, or a small incision. The place of endoscope entry is determined by the are of the body the doctor wishes to view.

Some endoscopes have a view piece that allows the doctor to see directly into the patient. Others have camera at the end, which sends video signals through fiber optic wires in the endoscope to a television monitor in the procedure room. This allows the doctor and others to get a clear, enlarged view of the area of interest, and can allow for recording the procedure to review later if there are any questions.

In most cases the patient is mildly or heavily sedated during the procedure. Many patients actually sleep through the majority of the procedure. The area under investigation may also receive local **anesthesia** if discomfort from the procedure is expected.

Many endoscopes allow the doctor not only to see the inside of the patient, but also to perform some additional procedures. Some endoscopes have a device for cauterizing as an available attachment, which can be used to stop internal bleeding in the area being investigated. Other endoscopes allow the doctor to cut and remove polyps during the procedure. Some endoscopes allows for the biopsy of suspicious tissue during the procedure, removing the need for an additional, usually more invasive procedure later.

One of the newest endoscopy technologies, capsule endoscopy, allows the physician to examine the esophagus, stomach, and small intestine. For this procedure, the patient swallows a capsule (slightly larger than a large vitamin) containing video chips, lights, and a transmitter. Rapid photos are made as the capsule travels through the digestive tract, and are transmitted to a receiver worn around the patient's waist. The capsule eventually passes in the stool, and images are downloaded from the receiver for the physician to evaluate. Limitations of capsule endoscopy include the inability to gather samples or remove polyps, and the fact the capsule battery sometimes fades before the capsule travels to the area targeted for inspection.

Precautions

The precautions for endoscopy vary depending on the type of endoscopy performed. Individuals who have conditions that require regular consumption of food or liquids may not be good candidates for endoscopy. Individuals who are allergic to one or more sedatives or anesthesia products should alert their doctor and health care team so that alternative medications can be found and special precautions can be taken.

Preparation

The preparation for an endoscopy depends heavily on the type of endoscopy being performed. The patient is generally instructed not to eat or drink for a certain amount of time before the procedure. If there is food in the upper digestive system this can reduce visibility, and **vomiting** can occur causing complications. If an endoscopy is being performed on the lower digestive tract the patient may be prescribed **laxatives** or one or more **enemas** before the procedure so that the area of interest is clearly visible.

The patient may be required to stop taking, or reduce the dosage of, some medications, supplements, or herbs before the procedure. Blood thinners can increase the risk of bleeding as a complication of the procedure, so individuals taking blood thinners may be asked to stop for a few days before the procedure. The patient is given specific instructions for his or her case, usually when the endoscopy is scheduled.

Aftercare

After the endoscopy the patient is often brought to a special recovery room to wait until the effects of any sedatives administered wear off, and to ensure there were no complications from the procedure. The

patient should arrange for transportation home after the procedure because he or she will not be able to drive after **sedation**. Generally, patients can begin to eat and drink again as desired after the procedure is over. The patient will generally begin to feel better quickly as any medication administered wears off, although some soreness may occur. The patient should usually allow the remainder of the day to rest after the procedure.

Risks

An endoscopy can result in soreness in the area in which the endoscopy was performed. Bloating and gas sometimes occur after endoscopies performed on the gastrointestinal tract. In rare cases endoscopy can cause bleeding, and in extremely rare cases can cause rupture or tearing of the intestinal wall. If anesthesia or sedatives were used these can have their own risks of complications. In most cases no serious complications result from endoscopy.

Results

An endoscopy produces pictures of the area being looked at so that the doctor can use them to assist in making a diagnosis. In some cases the endoscopy will also produce samples that can be examined under the microscope. The results of the endoscopy will vary depending on the reason it was performed, the area examined, and whether any biopsies were taken. A normal endoscopy will produce images that show healthy, normally functioning organs and tissues with no tears, growths, or bleeding. An abnormal endoscopy may show growths, bleeding, tearing of the intestinal wall, abnormal coloration, or a variety of other problems.

Robert Bockstiegel

Enemas

Definition

An enema is the insertion of a solution into the rectum and lower intestine.

Purpose

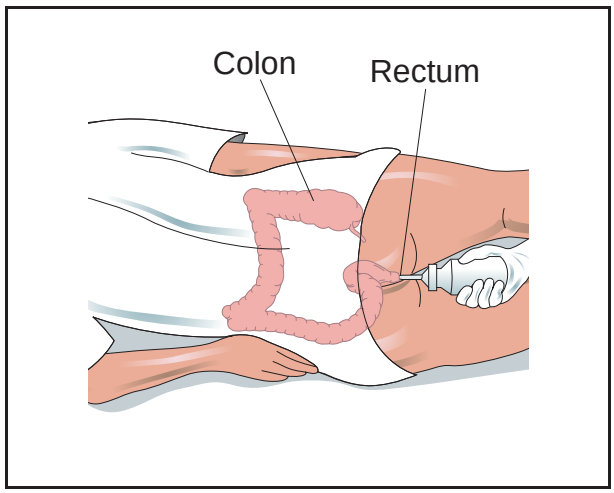
Enemas may be given for the following purposes:

- to remove feces when an individual is constipated or impacted,
- to remove feces and cleanse the rectum in preparation for an examination,
- to remove feces prior to a surgical procedure to prevent contamination of the surgical area,
- to administer drugs or anesthetic agents.

Precautions

The rectal tube used for infusion of the enema solution should be smooth and flexible to decrease the possibility of damage to the mucous membrane that lines the rectum. Tap water is commonly used for adults but should not be used for infants because of the danger of electrolyte (substance that conducts electric current within the body and is essential for sustaining life) imbalance. The colon absorbs water, and repeated tap water enemas can cause cardiovascular overload and electrolyte imbalance. Similarly, repeated saline enemas can cause increased absorption of fluid and electrolytes into the bloodstream, resulting in overload. Individuals receiving frequent enemas should be observed for overload symptoms that include **dizziness**, sweating, or **vomiting**.

WWW.BOOKBAZ.IR



Enemas may be given for the following purposes: to remove feces when an individual is constipated, or to remove feces and cleanse the rectum in preparation for an examination, or prior to surgery to prevent contamination. There are two types of enemas: the high enema, given to cleanse the large bowel, and the low enema, to cleanse only the lower bowel. *(Illustration by Electronic Illustrators Group. © Cengage Learning®.)*

Soap suds and saline used for cleansing enemas can cause irritation of the lining of the bowel, with repeated use or a solution that is too strong. Only white soap should be used; the bar should not have been previously used, to prevent infusing undesirable organisms into the individual receiving the enema. Common household detergents are considered too strong for the rectum and bowel. The commercially prepared castile soap is preferred, and should be used in concentration no greater than 5 cc soap to 1,000 cc of water.

Description

Cleansing enemas act by stimulation of bowel activity through irritation of the lower bowel, and by distention with the volume of fluid instilled. When the enema is administered, the individual is usually lying on the left side, which places the sigmoid colon (lower portion of bowel) below the rectum and facilitates infusion of fluid. The length of time it takes to administer an enema depends on the amount of fluid to be infused. The amount of fluid administered will vary depending on the age and size of the person receiving the enema, however general guidelines would be:

- Infant: 250 cc or less
- Toddler and preschooler: 500 cc or less
- School-aged child: 500–1,000 cc
- Adult: 750–1,000 cc

Some may differentiate between high and low enemas. A high enema, given to cleanse as much of the large bowel as possible, is usually administered at higher pressure and with larger volume (1,000 cc), and the individual changes position several times in order for the fluid to flow up into the bowel. A low enema, intended to cleanse only the lower bowel, is administered at lower pressure, using about 500 cc of fluid.

Oil retention enemas serve to lubricate the rectum and lower bowel, and soften the stool. For adults, about 150–200 cc of oil is instilled, while in small children, 75–150 cc of oil is considered adequate. Salad oil or liquid petrolatum are commonly used at a temperature of 91°F (32.8°C). There are also commercially prepared oil retention enemas. The oil is usually retained for one to three hours before it is expelled.

The rectal tube used for infusion of the solution, is usually made of rubber or plastic, has two or more openings at the end through which the solution can flow into the bowel. The distance to which the tube must be inserted is dependent upon the age and size of the patient. For adult, insertion is usually 3–4 in (7.5–10 cm); for children, approximately 2–3 in (5–7.5 cm); and for infants, only 1–1.5 in (2.5–3.75 cm). The rectal tube is lubricated before insertion with a water soluble lubricant to ease insertion and decrease irritation to the rectal tissues.

The higher the container of solution is placed, the greater the force in which the fluid flows into the patient. Routinely, the container should be no higher than 12 in (30 cm) above the level of the bed; for a high cleansing enema, the container may be 12–18 in (30–45 cm) above the bed level, because the fluid is to be instilled higher into the bowel.

Preparation

The solution used in the procedure is measured, mixed, and warmed before administration of the enema.

Aftercare

If necessary, a specimen will be collected for diagnostic evaluation. If the enema was given to alleviate **constipation**, the better approach to combatting constipation in the future is with a high fiber diet (five to six servings of whole grain foods) and adequate fluid intake (seven to eight glasses of water per day). Regular **exercise** and going to the bathroom when necessary will also help. If constipation is a chronic problem, medical help should be consulted to determine if there is underlying disorder.

KEY TERMS

Electrolyte—A substance that conducts electric current within the body and is essential for sustaining life.

Intestine—Also called the bowels and divided into large and small intestine, they extend from the stomach to the anus, where waste products exit the body. The small intestine is about 20 ft (6.1m) long and the large intestine, about 5 ft (1.5m) long.

Rectum—The portion of bowel just before the anus. The prefix *recto* is used with a variety of words in relation to conditions that affect the rectum.

Risks

Habitual use of enemas as a means to combat constipation can make the problem even more severe when their use is discontinued. Enemas should be used only as a last resort for treatment of constipation and with a doctor's recommendation. Enemas should not be administered to individuals who have recently had colon or rectal surgery, a **heart attack**, or who have an unknown abdominal condition or an irregular heartbeat.

Energy drinks

Definition

Energy drinks are advertised as being able to increase energy, stamina, and alertness. They contain a variety of additives and usually contain large amounts of **caffeine**.

Description

Energy drinks are marketed as having the ability to increase alertness, sharpen attention, and increase stamina. They typically contain large amounts of caffeine, sugars, and a variety of herbal and other ingredients. This category of drink does not include performance-enhancing drinks such as Gatorade that include sugars and electrolytes, but do not include caffeine or herbal supplements.

The first energy drink introduced in the United States was Red Bull, which entered the market in 1997. It quickly became popular with young adults, and other drink manufacturers soon entered the market. In 2011, energy drinks were estimated to be more than a $9 billion market in the United States alone. In 2013, sales of the drinks rose 6%, and sales of the drinks are particularly strong in convenience stores. Worldwide, energy drinks are among the fastest growing soft drinks, accounting for nearly US$26 billion in sales.

Energy drinks are primarily consumed by, and marketed to, individuals under the age of 35. They are most popular among high school and college students. One study found that more than 50% of college students had consumed an energy drink in the past month. And the drinks are appealing to younger people. The U.S. Centers for Disease Control and Prevention (CDC) found that more than 5% of high school students reported drinking at least one energy drink daily. It is estimated that between 20% and 30% of teenagers and young adults consume energy drinks on a regular basis.

The amount of caffeine in energy drinks varies widely, from about 85 mg to more than 500 mg per can. It is important to note that although the label information on many larger cans of energy drinks contain more than one serving, it is typical to consume the entire can at one time. Anyone examining the labels of energy drinks should note the number of servings and multiply the information accordingly.

Energy drinks typically are sold as **nutritional supplements** and not as food products. This means that they receive less regulatory scrutiny and oversight from the U.S. Food and Drug Administration (FDA) than many other food products. The FDA limits the amount of caffeine that can be in a 12 oz serving of soda to 71 mg, and the average soft drink contains about 37 mg of caffeine. The FDA does not limit the amount of caffeine in energy drinks. Energy drinks are also not required to be labeled with the amount of caffeine they contain.

Purpose

The purpose of energy drinks is to provide a short-term boost in attention, alertness, and feelings of general well-being. Some energy drinks also

WWW.BOOKBAZ.IR

ROBERT CADE (1927–2007)

Robert Cade earned his Bachelor of Science at the University of Texas, and then taught at the University of Florida College of Medicine.

In 1965, the Florida Gators football coach was concerned about the extreme dehydration of his players in the Florida heat. In need of a solution, he consulted with Cade. Cade worked with a team of doctors to develop a drink fortified with glucose and electrolytes. The initial formula tasted horrible, but after several iterations, the product was patented. Gatorade gained national attention during the 1967 Orange Bowl. The Gators defeated Georgia Tech, and the Georgia Tech coach said, "We didn't have Gatorade; that made the difference."

Gatorade is now a million dollar product, available in many flavors and sold worldwide. Cade was inducted into the University of Florida Athletic Hall of Fame in April 2007. In November of 2007, Cade died as a result of kidney failure.

advertise having additional benefits, such as increasing memory or containing **vitamins** that boost immunity.

Energy drinks are consumed for a wide variety of reasons. Athletes consume them to get a boost of energy before a game or workout. They are popular with students who believe that they help with attention while studying or with staying alert during late night study sessions. Energy drinks are also consumed by individuals who need to remain alert on the job or while working overnight shifts. In many cases, energy drinks are consumed for their taste, or to provide daily caffeine for individuals who are addicted to caffeine.

Risks

There are a wide variety of risks associated with drinking energy drinks, especially for children, teenagers, and young adults. Serious long-term health consequences including seizures and **stroke**, and even sudden deaths, have been reported as directly linked to energy drink consumption.

Energy drinks contain large amounts of caffeine. Caffeine in moderation generally is not considered dangerous, but in larger amounts it can cause health problems, especially in people with certain underlying medical conditions. For a healthy adult, the maximum recommended daily intake of caffeine is 400 mg. For children, the recommended maximum is 100 mg a day. Some energy drinks contain as many as 505 mg per can. Some of the risks associated with excessive caffeine consumption include:

- increased blood pressure
- nervousness
- difficulty concentrating
- irritability
- rapid heartbeat
- insomnia
- nausea

Individuals with underlying medical conditions such as irregular heartbeat, diabetes, or high blood pressure are at higher risk for serious complications from consuming excessive caffeine. The more caffeine consumed during the day, the higher the risk of adverse consequences.

In addition to caffeine, energy drinks typically contain large amounts of sugar and are high in calories. Some energy drinks contain more than 400 calories per can. Calories consumed through beverages do not usually cause the body to feel full, increasing the likelihood of overconsuming during the day. **Diets** high in refined sugars can lead to weight gain and **obesity**. Obesity increases the risk of type 2 diabetes, cardiovascular disease, and high **cholesterol** level, and possibly some cancers. Some energy drinks offer diet or sugar-free versions, but these contain artificial sweeteners that may have their own risks.

Energy drinks also contain a wide variety of herbal and vitamin supplements. Each supplement has its own risks, some of which are very serious. Many energy drinks contain supplements in higher levels than are required for good **nutrition**. In many cases, excess vitamins are excreted in the urine, but in some cases, they can build up in the body and cause serious health consequences. Some herbs and supplements can interact with medications. Individuals taking medications should consult their doctor or pharmacists before drinking energy drinks to ensure that there will not be any adverse interactions with the medications.

Mixing energy drinks with alcohol

Mixing energy drinks with alcohol is popular among college students and young adults. One study found that 27% of college students reported that they had mixed alcohol and an energy drink at least once in the previous month. This especially dangerous practice has lead to a number of deaths. The caffeine and other ingredients in energy drinks make the individual feel more alert, and they perceive themselves to be less inebriated than they actually are. The body's normal response to excessive alcohol consumption is to become sleepy, and eventually the individual typically falls asleep and thus stops drinking. Combining energy drinks with alcohol interrupts this process, so the individual does not become sleepy and continues to drink. This increases the likelihood of alcohol **poisoning**, which can be fatal.

The combination of energy drinks and alcohol is so dangerous that in 2010, the FDA banned the sale of drinks that contained both alcohol and caffeine. Drinks such as Four Loco and Joose had been popular with young adults, and were often sold in supermarkets and convenience stores on the shelf right next to energy drinks not containing alcohol. In some cases, a single can of these premixed drinks contained more caffeine than three cups of coffee and more alcohol than three beers. The FDA stepped in and issued the ban after increasing numbers of reports of deaths caused by the drinks. In 2014, the FDA announced that it would investigate the practice of companies adding caffeine to numerous food products, including water, waffles, candy, and gum.

Concerns about health hazards growing

The United States is not the only country concerned about energy drinks, and especially the combination of caffeine and alcohol in some drinks. In fall 2014, Russian lawmakers were considering a ban on the sale of energy drinks containing alcohol. The United Arab Emirates also banned the sale of any energy drinks to its citizens under age 20 in 2014.

Controversy has grown in the United States and around the world in recent years regarding energy drink marketing practices and health effects. Interest groups have criticized marketing they say is aimed at children and teens, and claims of hazards to heart health have arisen from use of the drinks, particularly from smaller energy shots. The attorneys general in several states brought action against the makers of 5-Hour Energy in 2014 for alleged false advertising for the product. Previous actions addressed marketing to children and potential health risks. In June 2011, the American Academy of Pediatrics released a report outlining the differences between sports drinks and energy drinks and warning that children should not consume energy drinks, which contain stimulants not found in sports drinks.

Benefits

Proponents of energy drinks suggest that energy drinks increase alertness, attention, stamina, and even improve cognitive abilities. Very few rigorous scientific studies have been done to investigate these claims. Energy drinks generally contain large amounts of sugar and caffeine. Sugar can temporarily increase alertness, although this increase is usually followed shortly by a "sugar crash," which causes feelings of sleepiness and can cause difficulty paying attention.

Caffeine is a stimulant that can temporarily increase feelings of alertness and reduce feelings of **fatigue**. The amount of caffeine in energy drinks varies greatly, and individuals should consume them with caution. While small amounts of caffeine can provide an energy boost, large amounts can lead to serious negative health consequences.

In addition to sugar and caffeine, most energy drinks contain a variety of other additives. Often these are herbal additives that are believed to have additional beneficial properties, such as increasing concentration, alertness, and boosting the immune system. Many of these additives actually contain additional caffeine or have effects similar to caffeine. This additional caffeine is not always included in the caffeine content listed on the label. Each additive should be researched because it could have many different benefits and risks.

Preparation

There is no preparation required for drinking energy drinks. However, it is important to check the label carefully and look up the risks and benefits of any ingredients that are not familiar. Many ingredients in energy drinks can have harmful side effects, especially for people with certain diseases and conditions.

Aftercare

After drinking an energy drink, a person should be alert to any changes that could indicate a serious health problem. Some signs of a serious problem include:

- dizziness
- faintness

WWW.BOOKBAZ.IR

KEY TERMS

Cholesterol—A waxy substance made by the liver and also acquired through diet. High levels in the blood may increase the risk of cardiovascular disease.

Obesity—Excessive weight, defined as a body mass index of 30 or above.

Type 2 diabetes—Formerly called adult-onset diabetes. In this form of diabetes, the pancreas either does not make enough insulin or cells become insulin resistant and do not use insulin efficiently.

- irregular heart beat
- shakiness or tremors
- nausea
- vomiting
- blurred vision

If any of these symptoms occur, a medical professional should be consulted immediately. These symptoms can be a sign that there is a serious health issue that if not treated immediately could lead to long-term health consequences and even death.

REVISED BY TERESA G. ODLE

Enhanced external counterpulsation

Definition

Enhanced external counterpulsation (EECP) is a noninvasive procedure in which a set of inflatable cuffs (much like blood pressure cuffs) mechanically compress the blood vessels in the patient's lower limbs to increase blood flow in the coronary arteries of the heart. The blood pressure cuffs (also called stockings) are wrapped around the patient's calves, lower thighs, and upper thighs. Computer technology, **electrocardiography**, and blood pressure monitors enable the pressure cuffs to be inflated and deflated in time with the patient's heartbeat and blood pressure.

Purpose

EECP is performed to restore blood flow to the heart and to relieve chest **pain** (**angina** pectoris) and ischemia. The goals of the procedure are to relieve the symptoms of **coronary artery disease**, enable the patient to resume a normal lifestyle, and lower the risk of a **heart attack** or other heart problems. EECP

may encourage blood vessels to open small channels (called collateral blood vessels) to eventually bypass blocked vessels and improve blood flow to the heart.

Demographics

The concept of counterpulsation is not new; it was first introduced in 1953 at Harvard, and refined in the late 1950s. Early models of EECP, however, used nonsequenced pulsation; that is, compression of the patient's blood vessels was performed simultaneously along the full length of the body. In the 1970s, researchers in China reported on a sequential compression system in which four sets of pressure cuffs were applied to the patient's legs, buttocks, and arms. Favorable reports about the effectiveness of sequential compression encouraged a research team at SUNY Stony Brook to develop the three-cuff EECP model in use in the early 2000s. The computerized technology currently available with EECP makes it a relatively new procedure compared to the systems used in the 1960s and early 1970s. As of 2008, it was available in about 200 centers across the United States.

EECP is used to treat patients with chronic stable angina, coronary artery disease, or high blood pressure. The U.S. Food and Drug Administration (FDA) approved EECP for the treatment of **congestive heart failure** (CHF) in the early 2000s. Researchers at the Ohio Heart and Vascular Center reported in 2006 that EECP improved **exercise** duration as well as quality of life in patients with CHF. The treatment may be appropriate for patients who are not eligible for such nonsurgical interventional procedures as balloon **angioplasty**, stent placement, rotablation, **atherectomy**, or brachytherapy. It may also be used for patients who do not qualify for such surgical treatments as **coronary artery bypass graft surgery**.

EECP is not the first-line treatment for angina. Rather, it is reserved for patients who have not achieved good results from medication or interventional management of their symptoms. To be eligible for EECP, a patient must have coronary artery disease that includes at least one heart vessel with at least 70% obstruction. In addition, the patient must have evidence of either an infarction or significant ischemia on a **stress test** with nuclear or echocardiographic imaging.

EECP may benefit patients with such other medical conditions as **erectile dysfunction**, **kidney disease**, eye disease, **diabetic neuropathy**, **restless legs syndrome**, and other circulatory disorders. More research is needed to evaluate the outcomes of EECP for these patients.

Many insurance providers and Medicare have approved EECP treatment for reimbursement. Medicare pays about $5,500 for the full series of 35 treatments.

Contraindications

EECP is not recommended for patients who have certain types of valve disease, uncontrolled **arrhythmias** (irregular heart rhythms), severe **hypertension**, uncontrolled congestive **heart failure**, significant blockages or **blood clots** in the leg arteries, or those who have had a recent **cardiac catheterization**, angioplasty, or bypass surgery. It should also not be given to pregnant women.

Description

While the patient lies on a bed, the leg cuffs are deflated and inflated with each heartbeat. A computer synchronizes the compression of the cuffs with the heartbeat. The electrocardiogram indicates when each heartbeat begins, triggering the cuffs to be mechanically deflated. As each heartbeat ends, the cuffs are mechanically inflated in sequential order, starting with the cuffs on the calves and working upward to the cuffs on the lower and then the upper thighs. The pressure produced by the inflation of the cuffs when the heart is at rest pushes the blood in the legs upward toward the heart. The deflating action that occurs just when the heart begins to beat reduces the work of the heart as it pumps blood to other parts of the body. Inflation is controlled by a pressure monitor that inflates the cuffs to about 300 mm Hg. When timed correctly, the procedure increases the cardiac output.

EECP treatments are performed on an outpatient basis and generally last one to two hours. Treatments must be repeated about five times a week for up to seven weeks to achieve improved circulation. This 35-hour regimen is generally followed because it was used in the first multicenter study of EECP in 1999.

Diagnosis and preparation

Preparation

The patient is usually instructed to wear tight-fitting seamless cycling pants or athletic tights to prevent chafing, one of the main adverse side effects.

Before the procedure, the patient's weight, blood pressure, pulse, and breathing rate are measured and recorded. The patient's legs are examined for areas of redness and signs of potential vascular problems.

WWW.BOOKBAZ.IR

KEY TERMS

Angina—Also called angina pectoris; chest pain or discomfort that occurs when diseased blood vessels restrict blood flow to the heart.

Aorta—The main artery that carries blood from the heart to the rest of the body; the largest artery in the body.

Artery—A vessel that carries oxygen-rich blood to the body.

Atherectomy—A nonsurgical technique for treating diseased arteries with a rotating device that cuts or shaves away obstructing material inside the artery.

Atria (singular, atrium)—The right and left upper chambers of the heart.

Balloon angioplasty—A nonsurgical technique for treating diseased arteries by temporarily inflating a tiny balloon inside an artery.

Beta blocker—An antihypertensive drug that limits the activity of epinephrine, a hormone that increases blood pressure.

Brachytherapy—The use of radiation during angioplasty to prevent the artery from narrowing again (a process called restenosis).

Calcium channel blocker—A drug that lowers blood pressure by regulating calcium-related electrical activity in the heart.

Cardiac catheterization—An invasive procedure used to create x rays of the coronary arteries, heart chambers and valves.

Collateral vessel—A side branch or network of side branches of a large blood vessel.

Coronary artery disease—Also called atherosclerosis, it is a buildup of fatty matter and debris in the coronary artery wall that causes narrowing of the artery.

Echocardiogram—An imaging procedure used to create a picture of the heart's movement, valves and chambers.

Electrocardiogram (ECG, EKG)—A test that records the electrical activity of the heart, using small electrode patches attached to the skin on the chest.

Infarction—An area of dead tissue caused by obstruction of the blood supply to that tissue.

Ischemia—Decreased blood flow to an organ, usually caused by constriction or obstruction of an artery.

Rotablation—A nonsurgical technique for treating diseased arteries in which a special catheter with a diamond-coated tip is guided to the point of narrowing in the artery. The catheter tip spins at high speed and grinds away the blockage or plaque on the artery walls.

Stent—A device made of expandable metal mesh that is placed (by using a balloon catheter) at the site of a narrowing artery. The stent remains in place to keep the artery open.

Stress test—A test that determines how the heart responds to stress.

Vein—A blood vessel that returns oxygen-depleted blood from various parts of the body to the heart.

Ventricles—The lower pumping chambers of the heart that propel blood to the lungs and the rest of the body.

The patient is asked to record his or her symptoms during the course of treatment to determine whether and how symptoms improve over time. The patient should record the severity and duration of troublesome symptoms, the time the symptoms occurred, and any activities that may have triggered the symptoms. This patient record is reviewed before each treatment session.

PATIENT EDUCATION. The healthcare team will ensure that the patient understands the potential benefits and risks of the procedure. Informative and instructional handouts are usually provided to explain the procedure. Because the procedure requires multiple outpatient visits (generally 35 visits over a seven-week period), the patient must be able to meet the treatment schedule.

INFORMED CONSENT. Informed consent is an educational process between healthcare providers and patients. Before any procedure is performed, the patient is asked to sign a consent form. Before signing the form, the patient should understand the nature and purpose of the diagnostic procedure or treatment; the risks and benefits of the procedure; and alternatives, including the option of not proceeding with the test or treatment. During the discussion about the procedure, the healthcare providers are available to answer all of the patient's questions.

SMOKING CESSATION. Patients who will undergo any procedure to treat cardiovascular disease are encouraged to stop **smoking** and using any tobacco products before the procedure, and to make a commitment to be a nonsmoker after the procedure. There are

several smoking cessation programs available in the community. The patient should ask a healthcare provider for more information if he or she needs help quitting smoking.

Aftercare

Discomfort

Patients report little or no discomfort during the procedure. Some people may feel tired after the first few treatments, but this loss of energy improves over time.

Lifestyle changes

To manage **heart disease**, the patient needs to make several lifestyle changes before and after the procedure, including:

- Quitting smoking. Smoking causes damage to blood vessels, increases the patient's blood pressure and heart rate, and decreases the amount of oxygen available in the blood.
- Managing weight. Maintaining a healthy weight, by watching portion sizes and exercising, is important. Being overweight increases the work of the heart.
- Participating in an exercise program. The cardiac rehabilitation exercise program is usually tailored for the patient, who will be supervised by professionals.
- Making dietary changes. Patients should eat a lot of fruits, vegetables, grains, and nonfat or low-fat dairy products, and reduce fats to less than 30% of all calories. Alcoholic beverages should be limited or avoided.
- Taking medications as prescribed. Aspirin and other heart medications may be prescribed, and the patient may need to take these medications for life.
- Following up with healthcare providers. The patient should visit the physician regularly for follow-up visits to control risk factors.

Risks

EECP is a relatively safe and effective treatment, and few adverse side effects have been reported. The main adverse side effect is chafing (skin irritation from the compression of the cuffs). To reduce or prevent this side effect, patients are instructed to wear tight-fitting cycling pants or athletic tights. Leg pain is another adverse side effect.

Results

The benefits of EECP are comparable to the results of angioplasty and coronary artery bypass graft surgery: 70–80% of patients experience significant improvement after EECP treatment for as long as five years. The largest research study on EECP indicates that after receiving treatment, patients used less medication, had fewer angina attacks with less severe symptoms, and increased their capacity to exercise without experiencing symptoms. EECP improves the patient's sense of well-being and overall quality of life, and in some cases, prolongs the patient's life. Benefits five years after EECP treatment are comparable to surgical outcomes.

The effects of EECP treatment last from three to five years and sometimes longer.

EECP does not prevent coronary artery disease from recurring; therefore, lifestyle changes are strongly recommended and medications are prescribed to reduce the risk of recurrent disease.

Alternatives

All patients with coronary artery disease can help improve their condition by making lifestyle changes such as quitting smoking, losing weight if they are overweight, eating healthful foods, reducing blood **cholesterol**, exercising regularly, and controlling diabetes and high blood pressure.

All patients with coronary artery disease should be prescribed medications to treat their condition. Such antiplatelet medications as **aspirin** or clopidogrel (Plavix) are usually recommended. Other medications used to treat angina may include **beta blockers**, nitrates, and angiotensin-converting enzyme (ACE) inhibitors. Medications may also be prescribed to lower lipoprotein levels, since elevated lipoprotein levels have been associated with an increased risk of cardiovascular problems.

Treatment with **vitamin E** is not recommended because it does not lower the rate of cardiovascular events in people with coronary artery disease. Although such **antioxidants** as vitamin C, beta-carotene, and probucol show promising results, they are not recommended for routine use. Treatment with **folic acid** and **vitamins** B_6 and B_{12} lowers **homocysteine** levels (reducing the risk for cardiovascular problems), but more studies are needed to determine if lowered homocysteine levels correlate with a reduced rate of cardiovascular problems in treated patients.

Such nonsurgical interventional procedures as balloon angioplasty, stent placement, rotablation, atherectomy, or brachytherapy can be performed to open a blocked artery.

WWW.BOOKBAZ.IR

Coronary artery bypass graft surgery is a surgical procedure in which one or more blocked coronary arteries are bypassed by a blood vessel graft to restore normal blood flow to the heart. These grafts usually come from the patient's own arteries and veins located in the leg, arm, or chest.

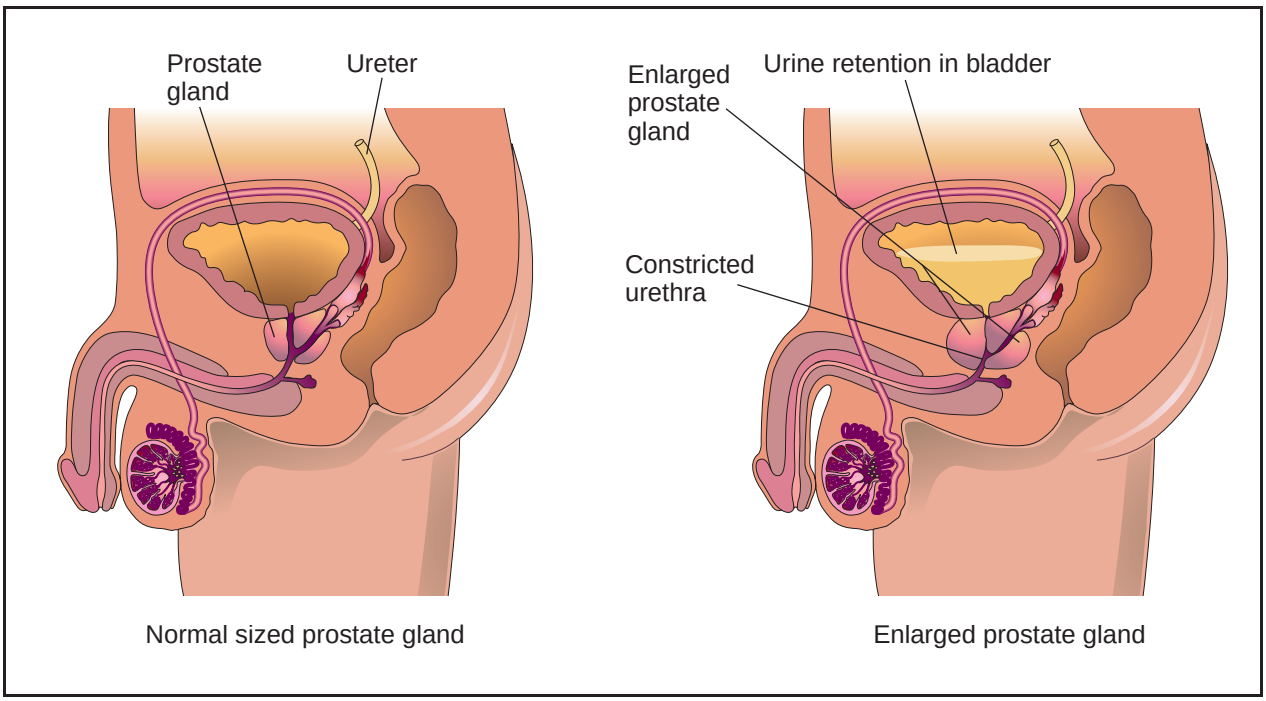
Enlarged prostate

Definition

A non-cancerous condition that affects many men past 50 years of age, enlarged prostate makes urinating more difficult by narrowing the urethra, a tube running from the bladder through the prostate gland. It can be effectively treated by surgery and by certain drugs.

Description

The common term for enlarged prostate is BPH, which stands for benign (non-cancerous) prostatic hyperplasia or hypertrophy. Hyperplasia means that the prostate cells are dividing too rapidly, increasing the total number of cells, and, therefore, the size of the organ itself. Hypertrophy simply means "enlargement." BPH is part of the **aging** process. The actual changes in the prostate may start as early as the 30s but take place very gradually, so that significant enlargement and symptoms usually do not appear until after age 50. Past this age the chances of the prostate enlarging and causing urinary symptoms become progressively greater. More than 40% of men in their 70s have an enlarged prostate. Symptoms generally appear



An enlarged prostate is a non-cancerous condition in which the narrowing of the urethra makes the elimination of urine more difficult. It most often occurs in men over age 50. *(Illustration by Electronic Illustrators Group. © Cengage Learning®.)*

between ages 55–75. About 10% of all men eventually will require treatment for BPH.

BPH has been viewed as a rare condition in African, Chinese, and other Asian peoples for reasons that are not clear.

Causes and symptoms

The cause of BPH is a mystery, but age-related changes in the levels of hormones circulating in the blood may be a factor. Whatever the cause, an enlarging prostate gradually narrows the urethra and obstructs the flow of urine. Even though the muscle in the bladder wall becomes stronger in an attempt to push urine through the smaller urethra, in time, the bladder fails to empty completely at each urination. The urine that collects in the bladder can become infected and lead to stone formation. The kidneys themselves may be damaged by infection or by urine constantly "backing up."

When the enlarging prostate gland narrows the urethra, a man will have increasing trouble starting the urine stream. Because some urine remains behind in the bladder, he will have to urinate more often, perhaps two or three times at night (nocturia). The need to urinate can become very urgent and, in time, urine may dribble out to stain a man's clothing. Other symptoms of BPH are a weak and sometimes a split stream and general aching or **pain** in the perineum (the area between the scrotum and anus). Some men may have considerable enlargement of the prostate before even mild symptoms develop.

If a man must strain hard to force out the urine, small veins in the bladder wall and urethra may rupture, causing blood to appear in the urine. If the urinary stream becomes totally blocked, the urine collecting in the bladder may cause severe discomfort, a condition called acute urinary retention. Urine that stagnates in the bladder can easily become infected. A burning feeling during urination and **fever** are clues that infection may have developed. Finally, if urine backs up long enough it may increase pressure in the kidneys, though this rarely causes permanent kidney damage.

Diagnosis

When a man's symptoms point to BPH, the first thing the physician will want to do is a **digital rectal examination**, inserting a finger into the anus to feel whether—and how much—the prostate is enlarged. A smooth prostate surface suggests BPH, whereas a distinct lump in the gland might mean **prostate cancer**. The next step is a blood test for a substance called

WWW.BOOKBAZ.IR

prostate-specific antigen or PSA. Between 30–50% of men with BPH have an elevated PSA level. This does not mean cancer by any means, but other measures are needed to make sure that the prostate enlargement is in fact benign. An **ultrasound** exam of the prostate, which is entirely safe and delivers no radiation, can show whether it is enlarged and may show that cancer is present.

If digital or ultrasound examination of the prostate raises the suspicion of cancer, most urologists will recommend that a prostatic tissue biopsy be performed. This is usually done using a lance-like instrument that is inserted into the rectum. It pierces the rectal wall and, guided by the physcian's finger, obtains six to eight pieces of prostatic tissue that are sent to the laboratory for microscopic examination. If cancer is present, the prognosis and treatment are changed accordingly.

A catheter placed through the urethra and into the bladder can show how much urine remains in the bladder after the patient urinates—a measure of how severe the obstruction is. Another and very simple test for obstruction is to have the man urinate into a uroflowmeter, which measures the rate of urine flow. A very certain—though invasive—way of confirming obstruction from an enlarged prostate is to pass a special viewing instrument called a cystoscope into the bladder, but this is not often necessary.

It is routine to check a urine sample for an increased number of white blood cells, which may mean there is infection of the bladder or kidneys. The same sample may be cultured to show what type of bacterium is causing the infection, and which **antibiotics** will work best. The state of the kidneys may be checked in two ways: imaging by either ultrasound or injecting a dye (the intravenous urogram, or pyelogram); or a blood test for creatinine, which collects in the blood when the kidneys cannot eliminate it.

Treatment

Drugs

A class of drugs called alpha-adrenergic blockers, which includes phenoxybenzamine and doxazosin, relax the muscle tissue surrounding the bladder outlet and lining the wall of the urethra to permit urine to flow more freely. These drugs improve obstructive symptoms, but do not keep the prostate from enlarging. Other drugs (**e.g., finasteride**) do shrink the prostate and may delay the need for surgery. Symptoms may not, however, improve until the drug has been used for three months or longer. Antibiotic drugs are given promptly whenever infection is diagnosed. Some medications, including **antihistamines** and some **decongestants**, can make the symptoms of BPH suddenly worse and even cause acute urinary retention, and should be avoided.

Intermediate treatments

When drugs have failed to control symptoms of BPH but the physician does not believe that conventional surgery is yet needed, a procedure called transurethral needle ablation may be tried. In the office and using local **anesthesia**, a needle is inserted into the prostate and radiofrequency energy is applied to destroy the tissue that is obstructing urine flow. Another new approach is microwave hyperthermia, using a device called the Prostatron to deliver microwave energy to the prostate through a catheter. This procedure is done at an outpatient surgery center.

Surgery

For many years the standard operation for BPH has been transurethral resection (TUR) of the prostate. Under general or spinal anesthesia, a cystoscope is passed through the urethra and prostate tissue surrounding the urethra is removed using either a cutting instrument or a heated wire loop. The small pieces of prostate tissue are washed out through the scope. No incision is needed for TUR. There normally is some blood in the urine for a few days following the procedure. In a few men—less than 5% of all those having TUR—urine will continue to escape unintentionally. Other uncommon complications include a temporary rise in blood pressure with mental confusion, which is treated by giving salt solution. Impotence—the inability to achieve lasting penile erections—does occur, but probably in fewer than 10% of patients. A narrowing or stricture rarely develops in the urethra, but this can be treated fairly easily.

Alternatives to TUR, some only recently introduced, include:

- Laser ablation of the prostate. Laser energy is applied to the prostate through a special fiber passed through a cystoscope. The procedure is done in an operating room, and several patients have retained urine postoperatively.
- Transurethral incision of the prostate. Less invasive than standard TUR, an incision is made through the prostate to open up the part of the urethra passing through it. This may work well in men whose prostate is not grossly enlarged.
- Transurethral vaporization. A small roller ball is used to break up and vaporize the obstructing prostatic tissue, rather than cutting it away as in standard

KEY TERMS

Catheter—A rubber or plastic tube placed through the urethra into the bladder to remove excess urine when the flow of urine is cut off, or to prevent urinary infection.

Creatinine—One of the "waste" substances normally excreted by the kidneys into the urine. When urine flow is slowed, creatinine may collect in the blood and cause toxic effects.

Hyperplasia—A condition where cells, such as those making up the prostate gland, rapidly divide abnormally and cause the organ to become enlarged.

Hypertrophy—A technical term for enlargement, as in BPH (benign prostatic hypertrophy).

Urethra—In males, the tube that conducts urine from the bladder through the penis to the outside of the body. When narrowed by an enlarging prostate, symptoms of BPH develop.

Urinary retention—The result of progressive obstruction of the urethra by an enlarging prostate, causing urine to remain in the bladder even after urination.

TUR. This is equally successful but patients usually can leave the hospital within 24 hours, and there is less blood loss.

- If the prostate is greatly enlarged—as is the case in about 5–10% of those diagnosed–an incision is made to perform an open prostatectomy, removing the entire gland under direct vision.

Alternatives

An extract of the **saw palmetto** (*Serenoa repens* or *S. serrulata*) has been shown to stop or decrease the hyperplasia of the prostate. Symptoms of BPH will improve after taking the herb for one to two months, but continued use is recommended.

Prognosis

In a man without symptoms whose prostate is enlarged, it is hard to predict when urinary symptoms will develop and how rapidly they will progress. For this reasons some specialists (urologists) advise a period of "watchful waiting." When BPH is treated by conventional TUR, there is a small risk of complications but, in the great majority of men, urinary symptoms will be relieved and their quality of life will be much enhanced. In the future, it is possible that the less invasive forms of surgical treatment will be increasingly used to achieve results as good as those of the standard operation. It also is possible that new medications will be developed that shrink the prostate and eliminate obstructive symptoms so that surgery can be avoided altogether.

Prevention

Whether or not BPH is caused by hormonal changes in aging men, there is no known way of preventing it. Once it does develop and symptoms are present that interfere seriously with the patient's life, timely medical or surgical treatment will reliably prevent symptoms from getting worse. Also, if the condition is treated before the prostate has become grossly enlarged, the risk of complications is minimal. One of the potentially most serious complications of BPH, urinary infection (and possible infection of the kidneys), can be prevented by using a catheter to drain excess urine out of the bladder so that it does not collect, stagnate, and become infected.

Enterobacterial infections

Definition

Enterobacterial infections are disorders of the digestive tract and other organ systems produced by a group of gram-negative, rod-shaped bacteria called Enterobacteriaceae. Gram-negative means that the organisms do not retain the violet color of the dye used to make Gram stains. The most troublesome organism in this group is *Escherichia coli*. Other enterobacteria are species of *Salmonella*, *Shigella*, *Klebsiella*, *Enterobacter*, *Serratia*, *Proteus*, and *Yersinia*.

WWW.BOOKBAZ.IR

Description

Enterobacterial infections can be produced by bacteria that normally live in the human digestive tract without causing serious disease, or by bacteria that enter from the outside. In many cases these infections are nosocomial, which means that they can be acquired in the hospital. *Klebsiella* and *Proteus* sometimes cause **pneumonia**, ear and sinus infections, and urinary tract infections. *Enterobacter* and *Serratia* often cause bacterial infection of the blood (**bacteremia**), particularly in patients with weakened immune systems.

Diarrhea caused by enterobacteria is a common problem in the United States. It is estimated that each person in the general population has an average of 1.5 episodes of diarrhea each year, with higher rates in children, institutionalized people, and Native Americans. This type of enterobacterial infection can range from a minor nuisance to a life-threatening disorder, especially in infants, elderly persons, **AIDS** patients, and malnourished people. Enterobacterial infections are one of the two leading killers of children in developing countries.

Causes and symptoms

Causes

Enterobacterial infections in the digestive tract typically start when the organisms invade the mucous tissues that line the digestive tract. They may be bacteria that are already present in the stomach and intestines, or they may be transmitted by contaminated food and water. It is also possible for enterobacterial infections to spread by person-to-person contact. The usual incubation period is 12–72 hours.

***ESCHERICHIA COLI* INFECTIONS.** *E. coli* infections cause most of the enterobacterial infections in the United States. The organisms are categorized according to whether they are invasive or noninvasive. Noninvasive types of *E. coli* include what are called enteropathogenic *E. coli*, or EPEC, and enterotoxigenic *E. coli*, or ETEC. EPEC and ETEC types produce a bacterial poison (toxin) in the stomach that interacts with the digestive juices and causes the patient to lose large amounts of water through the intestines.

The invasive types of *E. coli* are called enterohemorrhagic *E. coli*, or EHEC, and enteroinvasive *E. coli,* or EIEC. These subtypes invade the stomach tissues directly, causing tissue destruction and bloody stools. EHEC can produce complications leading to **hemolytic-uremic syndrome** (HUS), a potentially fatal disorder marked by the destruction of red blood cells and kidney failure. EHEC has become a growing problem in the United States because of outbreaks caused by contaminated food. A particular type of EHEC known as O157:H7 has been identified since 1982 in undercooked hamburgers, unpasteurized milk, and apple juice. Between 2–7% of infections caused by O157:H7 develop into HUS.

Symptoms

The symptoms of enterobacterial infections are sometimes classified according to the type of diarrhea they produce.

WATERY DIARRHEA. Patients infected with ETEC, EPEC, some types of *Salmonella*, and some types of *Shigella* develop a watery diarrhea. These infections are located in the small intestine, result from bacterial toxins interacting with digestive juices, do not produce inflammation; and do not usually need treatment with **antibiotics**.

BLOODY DIARRHEA (DYSENTERY). Bloody diarrhea is sometimes called **dysentery**. It is produced by EHEC, EIEC, some types of *Salmonella*, some types of *Shigella*, and *Yersinia*. In dysentery, the infection is located in the colon, cells and tissues are destroyed, inflammation is present, and antibiotic therapy is usually required.

NECROTIZING ENTEROCOLITIS (NEC). Necrotizing enterocolitis (NEC) is a disorder that begins in newborn infants shortly after birth. Although NEC is not yet fully understood, it is thought that it results from a bacterial or viral invasion of damaged intestinal tissues. The disease organisms then cause the death (**necrosis**) of bowel tissue or **gangrene** of the bowel. NEC is primarily a disease of **prematurity**; 60–80% of cases occur in high-risk preterm infants. NEC is responsible for 2–5% of cases in newborn intensive care units (NICU). Enterobacteriaceae that have been identified in infants with NEC include *Salmonella*, *E. coli*, *Klebsiella*, and *Enterobacter*.

Diagnosis

Patient history

The diagnosis of enterobacterial infections is complicated by the fact that viruses, protozoa, and other types of bacteria can also cause diarrhea. In most cases of mild diarrhea, it is not critical to identify the organism because the disorder is self-limiting. Some groups of patients, however, should have stool tests. They include:

- patients with bloody diarrhea

- patients with watery diarrhea who have become dehydrated
- patients with watery diarrhea that has lasted longer than three days without decreasing in amount
- patients with disorders of the immune system

The patient history is useful for **public health** reasons as well as helping the doctor determine what type of enterobacterium may be causing the infection. The doctor will ask about the frequency and appearance of the diarrhea as well as other digestive symptoms. If the patient is nauseated and **vomiting**, the infection is more likely to be located in the small intestine. If the patient is running a **fever**, a diagnosis of dysentery is more likely. The doctor will also ask if anyone else in the patient's family or workplace is sick. Some types of enterobacteriaceae are more likely to cause group outbreaks than others. Other questions include the patient's food intake over the last few days and whether he or she has recently traveled to countries with **typhoid fever** or **cholera** outbreaks.

Physical examination

The most important parts of the **physical examination** are checking for signs of severe fluid loss and examining the abdomen to rule out typhoid fever. The doctor will look at the inside of the patient's mouth and evaluate the skin for signs of **dehydration**. The presence of a skin rash and an enlarged spleen suggests typhoid rather than a bacterial infection. If the patient's abdomen hurts when the doctor examines it, a diagnosis of dysentery is more likely.

Laboratory tests

The most common test that is used to identify the cause of diarrhea is the stool test. Examining a stool sample under a microscope can help to rule out parasitic and protozoal infections. Routine stool cultures, however, cannot be used to identify any of the four types of *E. coli* that cause intestinal infections. ETEC, EPEC, and EIEC are unusual in the United States and can usually be identified only by specialists in research laboratories. Because of concern about EHEC outbreaks, however, most laboratories in the United States can now screen for O157:H7 with a test that identifies its characteristic toxin. All patients with bloody diarrhea should have a stool sample tested for *E. coli* O157:H7.

Treatment

The initial treatment of enterobacterial diarrhea is usually empiric. Empiric means that the doctor treats the patient on the basis of the visible symptoms and professional experience in treating infections, without waiting for laboratory test results. Since the results of stool cultures can take as long as two days, it is important to prevent dehydration. The patient will be given fluids to restore the electrolyte balance and paregoric to relieve abdominal cramping.

Newborn infants and patients with immune system disorders will be given antibiotics intravenously once the organism has been identified. Gentamicin, tobramycin, and amikacin are being used more frequently to treat enterobacterial infections because many of the organisms are becoming resistant to ampicillin and cephalosporin antibiotics.

Alternatives

Alternative treatments for diarrhea are intended to relieve the discomfort of abdominal cramping. Most alternative practitioners advise consulting a medical doctor if the patient has sunken eyes, dry eyes or mouth, or other signs of dehydration.

Herbal medicine

Herbalists may recommend cloves taken as an infusion or ginger given in drop doses to control intestinal cramps, eliminate gas, and prevent vomiting. Peppermint (*Mentha piperita*) or chamomile (*Matricaria recutita*) tea may also ease cramps and intestinal spasms.

Homeopathy

Homeopathic practitioners frequently recommend *Arsenicum album* for diarrhea caused by contaminated food, and *Belladonna* for diarrhea that comes on suddenly with mucus in the stools. *Veratrum album* would be given for watery diarrhea, and *Podophyllum* for diarrhea with few other symptoms.

Prognosis

The prognosis for most enterobacterial infections is good; most patients recover in about a week or 10 days without needing antibiotics. HUS, on the other hand, has a mortality rate of 3–5% even with intensive care. About one-third of the survivors have long-term problems with kidney function, and another 8% develop high blood pressure, seizure disorders, and blindness.

Prevention

The World Health Organization (WHO) offers the following suggestions for preventing enterobacterial infections, including *E. coli* O157:H7 dysentery:

WWW.BOOKBAZ.IR

KEY TERMS

Dysentery—A type of diarrhea caused by infection and characterized by mucus and blood in the stools.

Empirical treatment—Medical treatment that is given on the basis of the doctor's observations and experience.

Escherichia coli—A type of enterobacterium that is responsible for most cases of severe bacterial diarrhea in the United States.

Hemolytic-uremic syndrome (HUS)—A potentially fatal complication of *E. coli* infections characterized by kidney failure and destruction of red blood cells.

Necrotizing enterocolitis (NEC)—A disorder in newborns caused by bacterial or viral invasion of vulnerable intestinal tissues.

Nosocomial infections—Infections acquired in hospitals.

Toxin—A poison produced by certain types of bacteria.

- Cook ground beef or hamburgers until the meat is thoroughly done. Juices from the meat should be completely clear, not pink or red. All parts of the meat should reach a temperature of 158°F (70°C) or higher.
- Do not drink unpasteurized milk or use products made from raw milk.
- Wash hands thoroughly and frequently, especially after using the toilet.
- Wash fruits and vegetables carefully, or peel them. Keep all kitchen surfaces and serving utensils clean.
- If drinking water is not known to be safe, boil it or drink bottled water.
- Keep cooked foods separate from raw foods, and avoid touching cooked foods with knives or other utensils that have been used with raw meat.

Enterobiasis

Definition

Enterobiasis, or pinworm infection as it is commonly called, is an intestinal infection caused by the parasitic roundworm called *Enterobius vermicularis*. The most common symptom of this irritating, but not particularly dangerous, disease is **itching** around the anal area.

Description

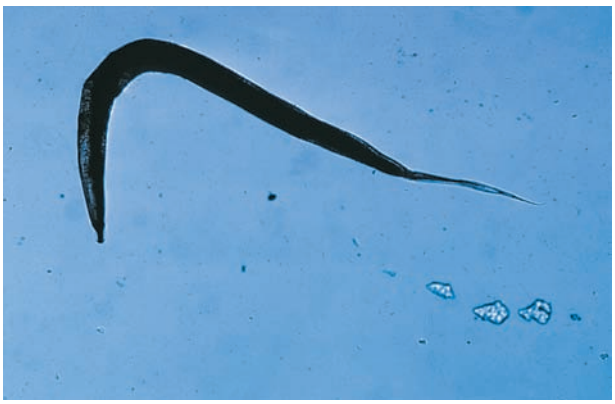
Enterobiasis is also called seatworm infection or oxyuriasis. In the United States, enterobiasis is the most common worm infection, and some estimate that approximately 10% of the United States population is infected. Worldwide, approximately 200 million people are infected. Enterobiasis can affect people of any age, but is most common among children ages 5–14 and particularly affects those in the daycare setting.

Causes and symptoms

The disease is highly contagious and is caused by a parasitic worm called *Enterobius vermicularis*. The adult female worm is about the size of a staple (approximately 0.4 in [1 cm long] and 0.02 in [0.5 mm] wide) and has a pointed tip. The disease is transmitted by ingesting the eggs of the pinworm. These eggs travel to the small intestine where, after approximately one month, they hatch and mature into adult worms. During the night, the female adult worms travel to the area around the anus and deposit eggs in the folds of the anal area. A single female pinworm can lay 10,000 eggs and, after laying eggs, dies. The eggs are capable of causing infection after six hours at body temperature.

Significant itching in the anal region is caused by the movement of the adult worm as the eggs are deposited. When an individual scratches the anal region, the tiny eggs get under the finger nails and in the underwear and night clothes. Anything the individual touches with the contaminated fingers, for example, toys, bedding, blankets, bathroom door knobs, or sinks, becomes contaminated. The eggs are very hardy and can live on surfaces for two to three weeks. Anyone touching these contaminated surfaces can ingest the eggs and become infected. An individual can also become infected by inhaling and swallowing the eggs, for example, when the bedcovers are shaken.

Many individuals with enterobiasis exhibit no symptoms. When present, however, symptoms of the infection begin approximately two weeks after ingesting



The pinworm of the genus *Enterobius* is the source of enterobiasis infestation occurring in children. *(Photo Researchers, Inc.)*

the pinworm eggs. The main symptom is itching around the anus. Because the itching intensifies at night, when the female worms comes to the anus to lay eggs, it often leads to disrupted sleep and irritability. Poor sleeping at night in small children can be related to pinworms. Occasionally, the itching causes some bleeding and bruising in the region, and secondary bacterial infections can occur. In females, the itching may spread to the vagina and sometimes causes an infection of the vaginal region (**vaginitis**). Enterobiasis usually lasts one to two months.

Diagnosis

First, a physician will rule out other potential causes of the itching, such as **hemorrhoids**, lice, or fungal or bacterial infection. Once these have been ruled out, an accurate diagnosis of enterobiasis will require that either the eggs or the adult worms are detected. Rarely, the adult worms are seen as thin, yellowish-white threads, about 0.4 in (1 cm) long, in the stools of the infected person. Usually, an hour or so after the individual goes to sleep, the adult female worms may be seen moving around laying eggs if a flashlight is shone at the rectal area.

An easier method is to observe the eggs under the microscope. In order to collect a specimen for laboratory diagnosis, the physician may provide a paddle with a sticky adhesive on one side, or an individual may be instructed to place a piece of shiny cellophane tape sticky side down against the anal opening. The best time to perform this test is at night or as soon as the individual wakes up in the morning, before having a bowel movement or taking a bath or shower. The pinworm eggs will stick to the tape, which can then be placed on a specimen slide. When under a microscope in the laboratory, the eggs will be clearly visible.

Treatment

In order to treat the disease, either mebendazole (Vermox) or pyrantel pamoate (Pin-X) will be given in two oral doses spaced two weeks apart. These medications eradicate the infection in approximately 90% of cases. Re-infection is common and several treatments may be required. Because the infection is easily spread through contact with contaminated clothing or surfaces, it is recommended that all family members receive the therapeutic dose. Sometimes a series of six treatments are given, each spaced two weeks apart. If family members continue to be infected, a source outside the house may be responsible.

To relieve the rectal itching, a shallow warm bath with either half a cup of table salt, or Epsom salts is recommended. Also, application of an ointment containing zinc oxide or regular petroleum jelly can be used to relieve rectal itching.

Prognosis

Pinworms cause little damage and can be easily eradicated with proper treatment. Full recovery is expected.

Prevention

The disease can be prevented by treating all the infected cases and thus eliminating the source of infection. Some ways to keep from catching or spreading the disease include the following recommendations:

- wash hands thoroughly before handling food and eating
- keep finger nails short and clean
- avoiding scratching the anal area
- take early morning showers to wash away eggs deposited overnight
- once the infection has been identified, and treatment is started, change the bed linen, night clothes, and underwear daily
- machine wash linens in hot water and dry with heat to kill any eggs
- open the blinds or curtains since eggs are sensitive to sunlight

WWW.BOOKBAZ.IR

KEY TERMS

Anus—The opening through which feces are eliminated.

Hemorrhoid—An area around the anus where veins become dilated and the tissue swells, causing itching and pain.

Rectum—The end of the large intestine in which feces collects for elimination through the anus.

Vaginitis—Inflammation of the vagina.

Enterostomy

Definition

An enterostomy is an operation in which the surgeon makes a passage into the patient's small intestine through the abdomen with an opening to allow for drainage or to insert a tube for feeding. The opening is called a stoma, from the Greek word for mouth. Enterostomies may be either temporary or permanent. They are classified according to the part of the intestine that is used to create the stoma. If the ileum, which is the lowest of the three sections of the small intestine, is used to make the stoma, the operation is called an ileostomy. If the jejunum, which is the middle section of the small intestine, is used, the operation is called a jejunostomy. Some people use the word *ostomy* as a word that covers all types of enterostomies.

Purpose

Enterostomies are performed in order to create a new opening for the passage of fecal matter when normal intestinal functioning is interrupted or when diseases of the intestines cannot be treated by medications or less radical surgery. Some situations that may require enterostomies include:

- Healing of inflamed bowel segments. Enterostomies performed for this reason are usually temporary.
- Emergency treatment of gunshot or other penetrating wounds of the abdomen. An enterostomy is needed to prevent the contents of the intestine from causing a serious inflammation of the inside of the abdominal cavity (peritonitis). These enterostomies are also often temporary.
- Placement of a tube for enteral feeding. Enteral feeding is a method for conveying nutritional solutions directly into the stomach or jejunum through a tube. Tube enterostomies may be long-term but are not permanent.
- Removal of diseased sections of the intestines. Ileostomies performed for this reason are permanent. The most common disorders requiring permanent ileostomy are Crohn's disease, familial polyposis, and ulcerative colitis. Familial polyposis and ulcerative colitis are serious health risks because they can develop into cancer.
- Treatment of advanced cancer or other causes of intestinal obstruction.

Precautions

Enterostomies are usually performed only as emergency treatments for traumatic injuries in the abdomen or as final measures for serious disorders of the intestines. Most patients do not refuse to have the operation performed when the need for it is explained to them. A small minority, however, refuse enterostomies because of strong psychological reactions to personal disfigurement and the need to relearn bowel habits.

Description

Ileostomy

Ileostomies represent about 25% of enterostomies. They are performed after the surgeon removes a diseased colon and sometimes the rectum as well. The most common ileostomy is called a Brooke ileostomy after the English surgeon who developed it. In a Brooke ileostomy, the surgeon makes the stoma in the lower right section of the abdomen. The ileum is pulled through an opening (incision) in the muscle layer. The surgeon then turns the cut end of the intestine inside out and sews it to the edges of the hole. He or she then positions an appliance for collecting the fecal material. The appliance consists of a plastic bag that fits over the stoma and lies flat against the abdomen. The patient is

taught to drain the bag from time to time during the day. Ileostomies need to be emptied frequently because the digested food contains large amounts of water. Shortly after the operation, the ileostomy produces 1–2 qt. (0.9–1.9 L) of fluid per day; after a month or two of adjustment, the volume decreases to 1–2 pt (0.5–0.9 L) per day.

KOCK POUCH (CONTINENT ILEOSTOMY). The Kock pouch is a variation of the basic ileostomy and is named for its Swedish inventor. In the Kock technique, the surgeon forms a pouch inside the abdominal cavity behind the stoma that collects the fecal material. The stoma is shaped into a valve to prevent fluid from leaking onto the patient's abdomen. The patient then empties the pouch several times daily by inserting a tube (catheter) through the valve. The Kock technique is sometimes called a continent ileostomy because the fluid is contained inside the abdomen. It is successful in 70–90% of patients who have it done.

Jejunostomy

A jejunostomy is similar to an ileostomy except that the stoma is placed in the second section of the small intestine rather than the third. Jejunostomies are performed less frequently than ileostomies. They are almost always temporary procedures.

Tube enterostomies

Tube enterostomies are operations in which the surgeon makes a stoma into the stomach itself or the jejunum in order to insert a tube for liquid nutrients. Tube enterostomies are performed in patients who need tube feeding for longer than six weeks, or who have had recent mouth or nose surgery. As long as the patient's intestinal tract can function, **tube feedings** are considered preferable to intravenous feeding. Enteral **nutrition** is safer than intravenous fluids and helps to keep the patient's digestive tract functioning.

Preparation

Preoperative preparation includes both patient education and physical preparation.

Patient education

If the patient is going to have a permanent ileostomy, the doctor will explain what will happen during the operation and why it is necessary. Most patients are willing to accept an **ostomy** as an alternative to the chronic **pain** and **diarrhea** of ulcerative **colitis** or the risk of cancer from other intestinal disorders. The patient can also meet with an enterostomal therapist (ET) or a member of the United Ostomy Association, which is a support group for people with ostomies.

Medical preparation

The patient is prepared for surgery with an evaluation of his or her nutritional status, possible need for blood transfusions, and **antibiotics** if necessary. If the patient does not have an intestinal obstruction or severe inflammation, he or she may be given a large quantity of a polyethylene glycol (PEG) solution to cleanse the intestines before surgery.

Aftercare

Aftercare of an enterostomy is both psychological and medical.

Medical aftercare

If the enterostomy is temporary, aftercare consists of the usual monitoring of surgical **wounds** for infection or bleeding. If the patient has had a permanent ileostomy, aftercare includes learning to use the appliance or empty the Kock pouch; learning to keep the stoma clean; and readjusting bathroom habits. Recovery takes a long time because major surgery is a **shock** to the system and the intestines take several days to resume normal functioning. The patient's fluid intake and output will be checked frequently to minimize the risk of **dehydration**.

Patient education

Ileostomy patients must learn to watch their fluid and salt intake. They are at greater risk of becoming dehydrated in hot weather, from **exercise**, or from diarrhea. In some cases they may need extra bananas or orange juice in the diet to keep up the level of potassium in the blood.

Patient education includes social concerns as well as physical self-care. Many ileostomy patients are worried about the effects of the operation on their close relationships and employment. If the patient has not seen an ET before the operation, the aftercare period is a good time to find out about self-help and support groups. The ET can also evaluate the patient's emotional reactions to the ostomy.

Risks

Enterostomies are not considered high-risk operations by themselves. About 40% of ileostomy patients have complications afterward, however; about 15%

WWW.BOOKBAZ.IR

KEY TERMS

Crohn's disease—A disease of the intestines that causes inflammation leading to scarring, thickening of the walls of the intestine, and eventual obstruction.

Duodenum—The first of the three segments of the small intestine. The duodenum connects the stomach and the jejunum.

Enteral nutrition—A technique for feeding patients with liquid formulas conveyed directly into the stomach or jejunum through tubes.

Enterostomal therapist (ET)—A specialized counselor, usually a registered nurse, who provides ostomy patients with education and counseling before the operation. After surgery, the ET helps the patient learn to take care of the stoma and appliance, and offers long-term emotional support.

Familial polyposis—A disease that runs in families in which lumps of tissue (polyps) form inside the colon. Familial polyposis may develop into cancer.

Ileum—The third segment of the small intestine, connecting the jejunum and the large intestine.

Jejunum—The second of the three segments of the small intestine, connecting the duodenum and the ileum.

Kock pouch—A type of ileostomy in which the surgeon forms an artificial rectum from a section of the ileum. A Kock pouch is sometimes called a continent ileostomy because it is drained with a tube.

Ostomy—A common term for all types of enterostomies.

Stoma—The surgically constructed mouth or passage between the intestine and the outside of the patient's body.

Tube enterostomy—An enterostomy performed to allow the insertion of a feeding tube into the jejunum or stomach.

Ulcerative colitis—A disease of the colon characterized by inflammation of the mucous lining, ulcerated areas of tissue, and bloody diarrhea.

require minor surgical corrections. Possible complications include:

- skin irritation caused by leakage of digestive fluids onto the skin around the stoma; irritation is the most common complication of ileostomies
- diarrhea
- the development of abscesses
- gallstones or stones in the urinary tract
- inflammation of the ileum
- odors can often be prevented by a change in diet
- intestinal obstruction
- a section of the bowel pushing out of the body (prolapse)

Results

Normal results include recovery from the surgery with few or no complications. About 95% of people with ostomies recover completely, are able to return to work, and consider themselves to be in good health. Many ileostomy patients enjoy being able to eat a full range of foods rather than living on a restricted diet. Some patients need to be referred to psychotherapists to deal with depression or other emotional problems after the operation.

Rebecca J. Frey, PhD

Enterovirus infections

Definition

Enteroviruses are so named because they reproduce initially in the gastrointestinal tract after infection occurs. Despite, this, they usually do not lead to intestinal symptoms; rather it is their spread to organs, such as the nervous system, heart, skin, and others that causes disease. Enteroviruses are part of a larger group of viruses known as Picornaviruses. The word comes from the combination of "pico" (Spanish, meaning "a little bit"), and RNA (ribonucleic acid, an important component of genetic material).

Description

There are four groups of enteroviruses: Coxsackievirus, Echovirus, ungrouped Enterovirus, and Y Poliovirus.

Viruses are generally divided into those that use DNA (deoxyribonucleic acid) or RNA as their genetic

material; all enteroviruses are RNA viruses. They are found worldwide, but infection is more common in areas of poor hygiene and overcrowding.

Although most cases of enterovirus do not produce symptoms, some five to 10 million individuals in the United States each year suffer from one of the enteroviral diseases. Illness is more common in the very young. While there are close to 70 different strains of enteroviruses, over 70% of infections are caused by only 10 types.

The virus is most commonly transmitted by the fecal-oral route (contamination of fingers or objects by human waste material); in some instances transmission is through contaminated food or water. Passage of some strains of virus by way of air droplets can lead to respiratory illness. Infection of fetuses by way of the placenta also has been documented. Breast milk contains antibodies that can protect newborns.

The incubation period for most enteroviruses ranges from 2–14 days. In areas of temperate climate, infections occur mainly in the summer and fall.

Enterovirus D68

Enterovirus D68 (EV-D68) is one of more than 100 non-polio enteroviruses. It was first discovered in California in 1962. Since EV-D68 causes respiratory illness, the virus can be found in an infected person's respiratory secretions, such as saliva and nasal mucus. It likely spreads from person to person when an infected person coughs, sneezes, or touches a surface that is then touched by others. Infants, children, and teenagers are most likely to get infected with enteroviruses and become ill.

EV-D68 is diagnosed by doing specific lab tests on specimens from a person's nose and throat. Although hospitals and doctor's offices can test to detect the virus, most cannot do specific testing to determine the type of enterovirus, like EV-D68. The CDC and some state health departments can do this sort of testing.

In late summer and fall 2014, the United States experienced a nationwide outbreak of enterovirus D68 (EV-D68) associated with severe respiratory illness. Enterovirus D68 cases increased in people in several states who were examined and hospitalized with severe respiratory illness, relative to the number of cases reported in previous years. In October of 2014, The CDC developed and starting using a new, faster lab test for detecting EV-D68. They recommend that clinicians only consider EV-D68 testing for patients with severe respiratory illness and when the cause is unclear.

Causes and symptoms

Enteroviruses are believed to be the cause of at least 10 distinct illnesses. Once they enter the body, they multiply in the cells that line the gastrointestinal tract, and eventually reach sites of lymphatic tissue (such as the tonsils). While most of these diseases are of short duration and do not cause significant injury, some can produce severe illness. Each presents its own unique symptoms. The Infectious Diseases Society of America reminded physicians that infants with enteroviral infections often present early in their illnesses with no signs of fever, complicating diagnosis.

The main syndromes caused by the various enteroviruses are the following:

- Summer grippe (nonspecific febrile illness). This is the most common syndrome, and is characterized by flu-like symptoms of fever, headache, and weakness, that typically last three to four days. Many patients also develop upper respiratory symptoms and some nausea and vomiting. One of the major ways to distinguish this disease from influenza, is the fact that grippe most often occurs in the summer.
- Generalized disease of the newborn is a potentially serious infection in which infants from one week to three months of age develop a syndrome that can be difficult to distinguish from a severe bacterial infection. Fever, irritability, and decreased responsiveness or excessive sleepiness are the major symptoms. Inflammation of heart muscle (myocarditis), low blood pressure, hepatitis, and meningitis sometimes complicate the illness.
- Aseptic meningitis encephalitis is a well known syndrome caused by this group of viruses. In fact, enteroviruses are responsible for over 90% of cases of aseptic meningitis, and most often hit children and young adults. Headache, fever, avoidance of light, and eye pain are characteristic. Drowsiness may be prominent, and other symptoms include sore throat, cough, muscle pain, and rash. Occasionally, not only the meninges—the covering around the brain and spinal cord—is infected, but also brain tissue itself, producing encephalitis. The illness resolves after about a week or so, and permanent damage is unusual. Enteroviruses can also produce the Guillian-Barré syndrome, which involves weakness and paralysis of the extremities and even the muscles of respiration.
- Pleurodynia (Bornholm's disease) is due to viral infection and inflammation of the chest and abdominal muscles used for breathing. Pain occurs as acute episodes, lasting 30 minutes or so. Coxsackie B virus is the usual cause of the illness.

WWW.BOOKBAZ.IR

KEY TERMS

Antibiotic—A medication that is designed to kill or weaken bacteria.

Antibodies—Proteins that are formed by the body and play a role in defense against infection.

Meninges—Outer covering of the spinal cord and brain. Infection is called meningitis, which can lead to damage to the brain or spinal cord and lead to death.

- Myocarditis and/or pericarditis involves infection of the heart muscle (myocardium) and the covering around the heart (pericardium). Infants and young adults are the most susceptible, and for some reason, more than two-thirds of cases occur in males. The disease usually begins as an upper respiratory tract infection with cough, shortness of breath, and fever. Chest pain, increasing shortness of breath, irregularities of cardiac rhythm, and heart failure sometimes develop. Some patients wind up with long-term heart failure if the heart muscle is significantly affected.
- Exanthems is the medical term for rashes, and enterovirus is the number one cause of summer and fall rashes in children. They occur anywhere on the body, and often resemble diseases such as measles.
- Hand-foot-and-mouth disease occurs initially as a sore throat (often involving the tongue as well), and is followed by a rash on the hands, and sometimes the feet. The rash often forms small blisters, which lead to ulcers. Symptoms generally resolve within a week. A specific Coxsackievirus (A16) is the most frequent cause of this highly infectious disease.
- Herpangina is most often caused by one of the Coxsackie A viruses, and appears as the acute onset of fever and sore throat. This last symptom is particularly severe, as the virus produces multiple ulcers in the throat. Swallowing becomes very painful; symptoms can persist for several weeks.
- Acute hemorrhagic conjunctivitis involves viral infection of the conjunctiva, which is a covering around the eye. Pain, blurred vision, aversion to light, and a discharge from the eye are the main symptoms. Headache and fever occur in about one in five patients. The disease runs its course in about 10 days.

A number of other illnesses have been attributed to enteroviruses, including pneumonia and other respiratory infections, myositis or muscle inflammation, arthritis, and acute inflammation of the kidneys. It is clear then that these viruses produce a number of various illnesses, most often in younger age groups.

Diagnosis

In the majority of cases, diagnosis is based on the characteristic symptoms that the virus produces (such as the chest pain in pleurodynia). Rarely is it necessary to identify a specific strain of virus causing the illness. It is more important to be certain that the infection is due to a virus that does not require treatment with antibiotics.

Culture, or growing the organism outside of the body, is helpful only when obtained from areas that tend to indicate recent infection, such as from swollen joints, cerebrospinal fluid, or blood. Cultures from other areas, such as the throat, can be misleading. This is because the virus may remain for long periods of time in places with a large amount of lymphatic tissue. As a rule, cultures done early in the illness are more likely to identify the virus.

New techniques that involve identification of viral genetic material (PCR) are useful in certain cases, but are not indicated for routine testing.

Treatment

Enterovirus is capable of attacking many different organs and producing a variety of symptoms. Most infections are mild and improve without complications, requiring no specific therapy. When the virus attacks critical organs however, such as the heart, respiratory muscles, nervous system, etc., specialized care is often needed.

No effective antiviral medication for enterovirus has undergone investigation in patients, though some drugs appeared promising for the future. In some patients who are unable to produce antibodies (hypogammaglobunemia), administrating antibodies themselves is helpful.

Prognosis

The overall outlook for enterovirus infection depends on the organs involved, and the immune condition of the individual patient. Unless vital organs are involved or immunity is abnormal, infection causes few problems. On the other hand, patients who have

diseases that affect antibody production can develop chronic infection of the brain or meninges. A 2003 study found that enterovirus infections can increase the risk of type 1 diabetes in children who are genetically predisposed to diabetes. Further studies in 2013, including the Diabetes Prediction and Prevention (DIPP) study confirm these findings.

Prevention

In the hospital setting, the best means of avoiding transmission of infection is the use of good handwashing practices and other appropriate precautions (gowns and gloves for hospital staff). The virus is found in feces for up to one week after infection; therefore, precautions that isolate waste material (enteric precautions) will help decrease the chance of spreading the illness.

Environmental health

Definition

Environmental health is the field of public health related to all health issues that may arise in connection with the natural or human-made environments. The **World Health Organization (WHO)** defines environmental health as all of those "physical, chemical and biological factors external to a person, and all the related factors impacting behaviours."

Purpose

The purpose of environmental health is to use the principles of public health and environmental science to prevent and control contaminants in the natural and artificial environment, thus providing a safer and healthier milieu within which humans may live and work.

Description

The modern science of environmental health dates to the work of Sir Edwin Chadwick in the last quarter of the nineteenth century. Chadwick was a social reformer who studied living conditions in England's urban areas and concluded that filthy environmental conditions were major contributors to the generally poor health of residents of the area. His 1842 report to the English Parliament on *The Sanitary Condition of the Labouring Population* is generally considered to have been a "wake up" call to the government about the risks posed by environmental factors to the health of the average English citizen. In 1884, Chadwick founded the Association of Public Sanitary Inspectors, which survives today as the Chartered Institute of Environmental Health. Other nations have a much shorter history of formal acknowledgment of the health risks posed by environmental factors. In the United States, for example, the National Center for Environmental Health (NCEH) of the **Centers for Disease Control and Prevention (CDC)** was created only in 1980. The NCEH is the primary federal agency with responsibility for environmental health issues.

The field of environmental health is often divided into three major subdisciplines:

- Environmental epidemiology studies the effects of exposure to environmental hazards on human health. Such studies are always observational and retrospective in nature because it is unethical to design or conduct experiments in which humans are intentionally exposed to agents that can cause them

WWW.BOOKBAZ.IR

The earthquake of Van-Ercis on October 25, 2011 in Van, Turkey, killed 04 and injured 4,152. *(© Prometheus72/Shutterstock.com.)*

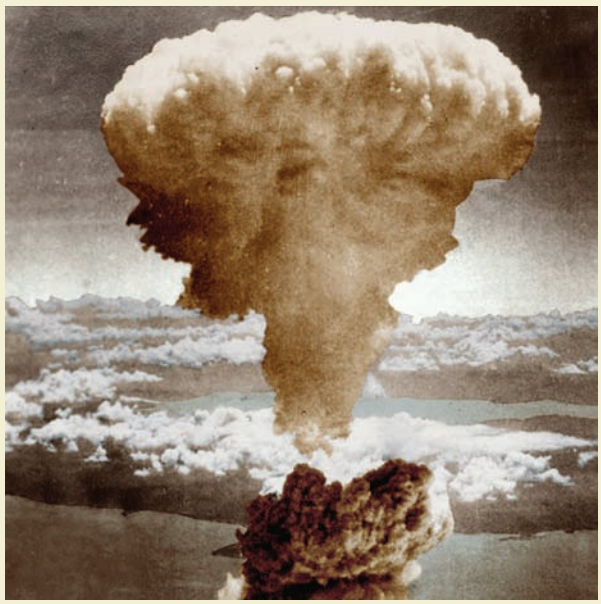
harm. A typical epidemiological study might attempt to measure, for example, the number of cases of cancer in a community located adjacent to a petroleum refinery compared to the number of cases in a community distant from such a source of pollution.

- Exposure science is somewhat similar to environmental epidemiology in that it involves studies in the field of the ways in which environmental factors can affect human health. The science is based on the fact that virtually all humans are constantly being exposed to agents that might have harmful effects on their health, but those effects differ significantly from person to person and from agent to agent. The exposure scientist works in the everyday environment of the average person, attempting to determine the range of health effects that can be expected from a range of exposure to such agents.
- Toxicology, on the other hand, relies on experiments conducted on nonhuman animals, such as rats and mice, to determine directly how environmental agents affect the health of those animals. The results of such studies are then commonly extrapolated to human health, with the understanding that human and nonhuman biology, while similar, are not identical in their response to environmental factors. One type of toxicological study might expose a population of rats to low levels of carbon monoxide over extended periods of time and then determine the effects of this exposure on their health. Assumptions about comparable exposure of humans to the same levels of carbon monoxide might then be made.

The field of environmental health covers a very wide range of subjects, as indicated by the topics of fact sheets published by WHO in the discipline. They include:

- Mercury and health
- Waste from healthcare activities
- Indoor air pollution and health
- Air quality and health
- Electromagnetic fields and public health: mobile phones
- Environmental and occupational cancers
- Elimination of asbestos-related diseases
- Dioxins and their effects on human health

HIROSHIMA AND NAGASAKI (1945)



The mushroom cloud of the first atomic bomb over Nagasaki, Japan, 9 August 1945. *(Photo by Apic/Getty Images)*

The American military's atomic bombings of Hiroshima and Nagasaki directly influenced Japan's unconditional surrender in World War II. In August of 1945, the first atomic bomb was dropped by the *Enola Gay*, an American B-29 bomber. The atomic bomb, known as "Little Boy", hit the Japanese city of Hiroshima, killing approximately 80,000 people and wiping out most of the town.

Three days later, a second atomic bomb was dropped on the major Japanese shipbuilding port of Nagasaki, killing approximately 40,000. With his country reeling from the devastating power of nuclear warfare, the Japanese emperor surrendered on August 15.

Survivors of the nuclear attacks have an increased health threat of radiation-induced cancer. The Radiation Effects Research Foundation (RERF), a Japanese/United States joint commission, monitors these atomic bomb survivors and studies the long-term health effects of radiation exposure.

- Climate change and health
- Sunbeds, tanning, and UV exposure
- Radon and cancer
- Base stations and wireless technologies
- Static electricity and magnetic fields
- Electromagnetic hypersensitivity
- Legionellosis
- Depleted uranium

Other topics of interest to environmental health workers are:

- Health effects of tattoos and other forms of body art
- Second-hand smoke
- Food safety
- Airborne and waterborne diseases
- Lead poisoning
- Land use policies
- Noise pollution
- Drinking water quality
- Vector control

The number and range of topics listed here provide a sense of the scope of environmental health issues in today's world. A large array of resources are available for both professional and laypersons in the field, including peer-reviewed journals such as *Environmental Health*, *Journal of Environmental Health*, *Environmental Health Perspectives*, *Journal of Toxicology and Environmental Health*, *Journal of Clinical Epidemiology*, *International Journal of Hygiene and Environmental Health*, *Environmental Research*, *International Journal of Occupational and Environmental Health*, *Environmental Health Insights*, *Toxicology Mechanisms and Methods*, and *Journal of Exposure Science and Environmental Epidemiology*. The U.S. National Library of Medicine (NLM) also maintains two resources of potential benefit and interest to the general public on environmental health issues, TOXNET and TOXMAP. TOXNET is a searachable resource that provides access to more than a dozen databases with information on environmental health issues in the United States, such as the Hazardous Substances Data Bank (HSDB), Toxicology Literature Online (TOXLINE), Developmental and Reproductive Toxicology Database (DART), and Genetic Toxicology Data Base (GENETOX). TOXNET can be accessed at http://toxnet.nlm.nih.gov/. NLM also maintains TOXMAP, which is a searchable database of all sites listed in the Environmental Protection Agency's Toxic Release Inventory (TRI) and the

Enzyme therapy

Definition

Enzyme therapy is a plan of dietary supplements of plant and animal enzymes used to facilitate the digestive process and improve the body's ability to maintain balanced metabolism.

Purpose

In traditional medicine, enzyme supplements are often prescribed for patients who have disorders that affect the digestive process, such as **cystic fibrosis**, Gaucher's disease, and **celiac disease**. A program of enzyme supplementation is rarely recommended for healthy patients. However, proponents of enzyme therapy believe that such a program is beneficial for everyone. They point to enzymes' ability to purify the blood, strengthen the immune system, enhance mental capacity, cleanse the colon, and maintain proper pH balance in urine. They feel that by improving the digestive process, the body is better able to combat infection and disease.

Some evidence exists that pancreatic enzymes derived from animal sources are helpful in cancer treatment. The enzymes may be able to dissolve the coating on cancer cells and may make it easier for the immune system to attack the cancer.

A partial list of the wide variety of complaints and illnesses that can be treated by enzyme therapy includes:

- AIDS
- anemia
- alcohol consumption
- anxiety
- acute inflammation
- back pain
- cancer
- colds
- chronic fatigue syndrome
- colitis

- constipation
- diarrhea
- food allergies
- gastritis
- gastric duodenal ulcer
- gout
- headaches
- hepatitis
- hypoglycemia
- infections
- mucous congestion
- multiple sclerosis
- nervous disorders
- nutritional disorders
- obesity
- premenstrual syndrome (PMS)
- stress

Description

Origins

Enzymes are protein molecules used by the body to perform all of its chemical actions and reactions. The body manufactures several thousands of enzymes. Among them are the digestive enzymes produced by the stomach, pancreas, small intestine, and the salivary glands of the mouth. Their energy-producing properties are responsible for not only the digestion of nutrients, but their absorption, transportation, metabolization, and elimination as well.

Enzyme therapy is based on the work of Dr. Edward Howell in the 1920s and 1930s. Howell proposed that enzymes from foods work in the stomach to pre-digest food. He advocated the consumption of large amounts of plant enzymes, theorizing that if the body had to use less of its own enzymes for digestion, it could store them for maintaining metabolic harmony. Four categories of plant enzymes are helpful in pre-digestion: protease, amylase, lipase, and cellulase. Cellulase is particularly helpful because the body is unable to produce it.

Animal enzymes, such as pepsin extracted from the stomach of pigs, work more effectively in the duodenum. They are typically used for the treatment of nondigestive ailments.

The seven categories of food enzymes and their activities

- amylase breaks down starches
- cellulase breaks down fibers
- lactase breaks down dairy products
- lipase breaks down fats
- maltase breaks down grains
- protease breaks down proteins
- sucrase breaks down sugars

Enzyme theory generated further interest as the human diet became more dependent on processed and cooked foods. Enzymes are extremely sensitive to heat, and temperatures above 118°F (48°C) destroy them. Modern processes of pasteurization, canning, and microwaving are particularly harmful to the enzymes in food.

Enzyme supplements are extracted from plants like pineapple and papaya and from the organs of cows and pigs. The supplements are typically given in tablet or capsule form. Pancreatic enzymes may also be given by injection. The dosage varies with the condition being treated. For nondigestive ailments, the supplements are taken in the hour before meals so that they can be quickly absorbed into the blood. For digestive ailments, the supplements are taken immediately before meals accompanied by a large glass of fluids. Pancreatic enzymes may be accompanied by doses of **vitamin A**.

Preparations

No special preparations are necessary before beginning enzyme therapy. However, it is always advisable to talk to a doctor or pharmacist before purchasing enzymes and beginning therapy.

Precautions

People with **allergies** to beef, pork, pineapples, and papaya may have allergic reactions to enzyme supplements. Tablets are often coated to prevent them from breaking down in the stomach, and usually should not be chewed or crushed. People who have difficulty swallowing pills can request enzyme supplements in capsule form. The capsules can then be opened and the contents sprinkled onto soft foods like applesauce.

Side effects

Side effects associated with enzyme therapy include **heartburn**, **nausea and vomiting**, **diarrhea**, bloating, gas, and **acne**. According to the principles of therapy, these are temporary cleansing symptoms. Drinking eight to 10 glasses of water daily and getting regular **exercise** can reduce the discomfort of these side effects. Individuals may also experience an increase in bowel

WWW.BOOKBAZ.IR

KEY TERMS

Celiac disease—A chronic disease characterized by defective digestion and use of fats.

Cystic fibrosis—A genetic disease that causes multiple digestive, excretion, and respiratory complications. Among the effects, the pancreas fails to provide secretions needed for the digestion of food.

Duodenum—The first part of the small intestine.

Gaucher's disease—A rare genetic disease caused by a deficiency of enzymes needed for the processing of fatty acids.

Metabolism—The system of chemical processes necessary for living cells to remain healthy.

movements, perhaps one or two per day. This is also considered a positive effect.

Plant enzymes are safe for pregnant women, although they should always check with a doctor before using enzymes. Pregnant women should avoid animal enzymes. In rare cases, extremely high doses of enzymes can result in a build up of uric acid in the blood or urine and can cause a break down of proteins.

Research and general acceptance

In the United States, the Food and Drug Administration (FDA) has classified enzymes as a food. Therefore, they can be purchased without a prescription. However, insurance coverage is usually dependent upon the therapy resulting from a doctor's orders.

Eosinophilic granuloma *see* **Histiocytosis X**

Eosinophilic pneumonia

Definition

Eosinophilic pneumonia is a group of diseases in which there is an above normal number of eosinophils in the lungs and blood.

Description

Eosinophilia is an increase in the number of eosinophils. Eosinophilic pneumonia is characterized by a large number of eosinophils in the lungs, usually in the absence of an infectious disease. Eosinophils are one of the white blood cells and are classified as a granulocyte. They are part of the non-specific immune system and participate in inflammatory reactions. Eosinophils contain cationic molecules that are useful for destroying infectious agents, especially heiminthic parasites (worms). There are several types of eosinophilic pneumonia. Loffler's pneumonia is a temporary infiltration of eosinophils into the lungs. The patient will feel tired, have a cough, spasms of the bronchial airway, and difficulty breathing. Loffler's pneumonia will clear spontaneously, but slowly over the course of about a month. Another form of eosinophilic pneumonia, pulmonary infiltrates with eosinophilia (PIE), is a more serious and potentially fatal disease. In PIE, the patient experiences asthma, pulmonary infiltrates, disorders of the peripheral nervous system, central nervous systems symptoms, and periarteritis nodosa.

Causes and symptoms

Pneumonia with eosinophils occurs as part of a hypersensitivity reaction. A hypersensitivity reaction is an over-reaction of the immune system to a particular stimulus. As part of the hypersensitive reaction, cells of the immune system are produced in increased numbers and migrate into areas targeted by the hypersensitivity reaction. In the case of eosinophilic pneumonia, the lungs are the target. Generally, eosinophilia pneumonia is not a reaction to an infection. There is a correlation between asthma and eosinophilic pneumonia. Eosinophilic pneumonia can also be caused by drugs and, in some people, by polluted air. The symptoms range from mild (coughing, wheezing, and shortness of breath) to severe and life threatening (severe shortness of breath and difficulty getting enough oxygen). The symptoms may resolve spontaneously or can persist for long periods of time. In a few cases, the disease may rapidly produce life-threatening pneumonia.

KEY TERMS

Infiltrates—Cells or body fluids that have passed into a tissue or body cavity.

Sputum—Material coughed up from the throat or lungs.

Diagnosis

Since eosinophilia is common to a number of conditions, the physician must rule out asthma and infection by helminths when diagnosing eosinophilic pneumonia. A whole blood count will reveal an increased number of eosinophils in the blood. An x ray of the lungs may show the presence of infiltrates (the eosinophils and fluid). If sputum is produced in coughing, eosinophils will be seen instead of the more normal profile of granulocytes seen when an infectious agent is present.

Treatment

Eosinophilic pneumonia may not respond to drugs used to treat asthma. Eosinophilic pneumonia is usually treated with steroids, particularly glucocorticosteroids. Steroids are not effective against infectious agents, but the main disease process in eosinophilic pneumonia is an inflammatory reaction, not a response to infection. When eosinophilia is produced as a consequence of asthma or an infection by helminths, treatment of the asthma or helminths will reduce the eosinophilia.

Epidemiology

Definition

Epidemiology is the study of the origin and cause of disease among populations.

Description

Epidemiology is an increasingly important part of public health because rapidly increasing human populations provide a fertile breeding ground for microbes. As the planet becomes more crowded and the distances that separate communities become smaller, infectious diseases that were once limited by geographic isolation now spread globally. In addition, many **viruses** and bacteria constantly evolve and shift among populations and across species. Epidemiologists use an array of skills to trace the source of disease.

The epidemiologist is concerned with the interactions of organisms and their environments. Environmental factors related to chronic and infectious diseases may include geographical features, climate, the concentration of pathogens in soil and water, or other factors. Some chronic diseases are infectious (e.g., cervical cancer caused by *human papilloma virus* [HPV], liver cancer caused by hepatitis B or C virus, and ulcers caused by *H. pylori* infections). Epidemiologists determine the numbers of individuals affected by a disease, the environmental contributions to disease, the causative agent or agents of disease, and the transmission patterns and lethality of disease.

Origins

Epidemiology is commonly thought to be limited to the study of infectious diseases, but that is only one aspect of the medical specialty. The epidemiology of the environment and lifestyles has been studied since Hippocrates' time. The first Nobel Prize in Medicine awarded to an epidemiologist was to Richard Doll for his work linking **smoking** to cancer. More recently, scientists have broadened the worldwide scope of epidemiology to studies of violence, of heart disease due to lifestyle choices, and to the spread of disease because of environmental degradation.

Epidemiologists at the Epidemic Intelligence Service (EIS) of the Centers for Disease Control and Prevention (CDC) have played important roles in landmark epidemiological investigations. Those include an investigation of Legionnaires disease in 1976, identification of tampons as a risk factor for toxic-shock syndrome, and investigation of the first cluster of cases that came to be called acquired

WWW.BOOKBAZ.IR

JOHN SNOW (1813–1858)

John Snow is known as the "father of epidemiology." During London's 1854 cholera epidemic, he connected the disease to microorganisms. He also gained notoriety for being one of the first medical professionals to use anesthesia.

Cholera was a fairly common health danger in the 1800s, resulting in death among approximately half of the affected patients. Snow determined that cholera was a contagious disease, spread by a microorganism usually transmitted via water and also found in patients' excrement. He published his findings in a pamphlet, "On the Mode of Communication of Cholera."

Snow's work with anesthesia began in the 1840s. Ether had been used as an anesthetic agent in limited cases, and Snow developed an inhaler that improved its effectiveness. His success led him to expand to other options, including chloroform. Snow famously administered chloroform to Queen Victoria during the births of two of her children.

immunodeficiency syndrome (**AIDS**). EIS officers are increasingly involved in the investigation of noninfectious disease problems, including the risk of injury associated with all-terrain vehicles and cluster deaths related to flour contaminated with parathion.

In the 1980s, epidemiologists connected AIDS to sexual contact, then to contaminated blood supplies, then proved the AIDS virus could cross the placental barrier, infecting babies born to HIV-infected mothers. Since the identification of the HIV virus responsible for AIDS, multiple genetic studies have established that the HIV virus passed into humans in Africa from chimpanzees that were probably butchered for meat about 100 years ago. Before being identified in the United States in the early 1980s, what eventually became known as AIDS syndrome was effectively hidden because it existed in people living in remote areas and occurred at low population levels. What is now known as AIDS was previously misdiagnosed as other diseases. For example, doctors in Africa often listed **leukemia** as the cause of death for persons who had AIDS.

Pandemic 2009 H1N1 Influenza

In April 2009 EIS officers investigated cases of a novel influenza in multiple states and quickly identified the cause as a new strain of the A (H1N1) influenza virus that likely emerged near Veracruz, Mexico. Although cases spread quickly and eventually resulted in a worldwide influenza pandemic, the rapid response by epidemiologists and other public health officials is credited with minimizing morbidity (illness and disability), mortality (death), and negative economic impacts from the pandemic.

Purpose

The epidemiological classification of disease deals with the incidence, distribution, and control of disorders of a population. Using the example of typhoid, a disease spread through contaminated food and water, scientists first must establish that the disease observed is truly caused by *Salmonella typhosa*, the typhoid organism. Investigators then must determine the number of cases, whether the cases were scattered over the course of a year or occurred within a short period, and the geographic distribution. It is critical that the precise locations of the diseased patients be established. In a hypothetical case, two widely separated locations within a city might be found to have clusters of cases of typhoid arising simultaneously. It might be that each of these clusters revolved around a family unit, suggesting that personal relationships could be important. Further investigation might disclose that all of the infected persons had dined at one time or at short intervals in a specific home, and that the person who had prepared the meal had visited a rural area, suffered a mild attack of the disease, and now was spreading it to family and friends by unknowingly contaminating of food.

An epidemic of **cholera** in the West African nation of Guinea-Bissau was tracked by CDC researchers using maps, interviews, and old-fashioned footwork through the country. An investigator eventually tracked the source of the cholera outbreak to contaminated shellfish. Epidemiologists also use high-tech tools. During a 2010 *Salmonella* outbreak in the United States, epidemiologists used pulse field gel electrophoresis (PFGE) to trace the source of the outbreak, which was linked to eggs sold to consumers under twenty-five different brand names by egg-producing farms that sold eggs to multiple packagers.

Changes in environment or social infrastructure can also fuel epidemics. For example, a breakdown in sanitation frequently offers conditions favorable to the spread of disease. An epidemic can result from an alteration in the environment that normally acts to limit disease.

In other cases, ecological imbalances can also increase the spread of disease. For example, an increase in mosquitoes, vectors for a number of diseases, can offer continuing challenges to public health officials. In

addition to tracking the origins of disease, epidemiologists may investigate the factors causing the increase in vector populations.

Lyme disease, which was tracked by epidemiologists from man to deer to the ticks that infest deer, is directly related to environmental changes. The lyme disease spirochete probably has been infecting ticks for a long time; museum specimens of ticks collected on Long Island in the l940s were found to be infected. Since then, tick populations in the Northeast have increased dramatically, triggering the epidemic. Epidemiologists and biologists concluded that the increase in ticks was linked to reforestation practices. Deer populations in those areas exploded, as did the numbers of *Ixodes dammini* ticks that feed on deer. The deer do not become ill, but when a tick bite infects a human host, the result can be lyme disease, which in severe cases causes crippling arthritis and memory loss.

Epidemiologists also study factors causing heart disease and cancer, developing a deeper understanding of the environmental, nutritional, and lifestyle factors that contribute to disease.

Epidermolysis bullosa

Definition

Epidermolysis bullosa (EB) is a group of rare inherited skin diseases that are characterized by the development of blisters following minimal pressure to the skin. Blistering often appears in infancy in response to simply being held or handled. In rarer forms of the disorder, EB can be life-threatening. There is no cure for the disorder. Treatment focuses on preventing and treating **wounds** and infection.

Description

Epidermolysis bullosa has three major forms and at least 16 subtypes. The three major forms are EB simplex, junctional EB, and dystrophic EB. These can range in severity from mild blistering to more disfiguring and life-threatening disease. Physicians diagnose the form of the disease based on where the blister forms in relation to the epidermis (the skin's outermost layer) and the deeper dermis layer.

The prevalence of epidermolysis varies among different populations. A study in Scotland estimated the prevalence to be one in 20,400. Researchers in other parts of the world estimate the prevalence to be one in 100,000. This variance is due to the variability of expression. Many cases of epidermolysis bullosa are often not accurately diagnosed and thus, are not reported.

WWW.BOOKBAZ.IR

Causes and symptoms

EB can be inherited as the result of a dominant genetic abnormality (only one parent carries the abnormal gene) or a recessive genetic abnormality (both parents carry the abnormal gene).

EB simplex results from mutations in genes responsible for keratin 5 and 14, which are proteins that give cells of the epidermis its structure. EB simplex is transmitted in an autosomal dominant fashion.

Dystrophic EB is caused by mutations in genes for type VII collagen, the protein contained in the fibers anchoring the epidermis to the deeper layers of the skin. The genetic mutations for junctional EB are found in the genes responsible for producing the protein Laminin-5. Dystrophic EB is an autosomal disorder and will only result if both parents transmit an abnormal gene during conception.

EB simplex, the most common form of EB, is the least serious form of the disease. In most affected individuals, the blisters are mild and do not scar after they heal. Some forms of EB simplex affect just the hands and feet. Other forms of EB simplex can lead to more widespread blistering, as well as hair loss and missing teeth. Recurrent blistering is annoying but not life threatening.

The second, or junctional, form of EB does not lead to scarring. However, skin on the areas prone to blistering, such as elbows and knees, often shrinks. In one variation of junctional EB, called gravis junctional EB of Herlitz, the blistering can be so severe that affected infants may not survive due to massive infection and **dehydration**.

The third form of EB, dystrophic EB, varies greatly in terms of severity, but more typically affects the arms and legs. In one variation, called Hallopeau-Siemens EB, repeated blistering and scarring of the hands and feet causes the fingers and toes to fuse, leaving them dysfunctional and with a mitten-like appearance.

Diagnosis

Physicians and researchers distinguish between the three major subtypes of EB based on which layer of the epidermis separates from the deeper dermis layer of the skin below. Patients suspected of having EB should have a fresh blister biopsied for review. This sample of tissue is examined under an electron microscope or under a conventional microscope using a technique called immunofluorescence, which helps to map the underlying structure.

KEY TERMS

Collagen—The main supportive protein of cartilage, connective tissue, tendon, skin, and bone.

Dermis—The layer of skin beneath the epidermis.

Epidermis—The outermost layer of the skin.

Keratin—A tough, nonwater-soluble protein found in the nails, hair, and the outermost layer of skin. Human hair is made up largely of keratin.

Knowing that a family member has EB can help establish the diagnosis, but it is possible that parents or siblings will show no sign of the disease, either because it is caused by a new genetic mutation, or because the parents are carriers of the recessive trait and do not display the disease.

Treatment

The most important treatment for EB is daily wound care. Because the skin is very fragile, care must be taken to be certain that dressing changes do not cause further damage. Tape should not be applied directly to skin and bandages should be soaked off. Infection is a major concern, so a topical antibiotic, such as bacitracin, mupirocin, or sulfadiazine, should be routinely applied. Among persons with recessive dystrophic EB, the anticonvulsant phenytoin is sometimes effective because it decreases production of an enzyme that breaks down collagen.

Prognosis

The prognosis of EB varies depending on the subtype of the disease. Individuals with EB simplex can live long, fulfilling lives. The severity of the junctional and dystrophic forms of EB can vary greatly. Infants affected with some forms of the disease often do not survive infancy; other forms can lead to severe scarring and disfigurement.

L. Fleming Fallon, Jr., MD, PhD, DrPH

Epididymitis

Definition

Epididymitis is an inflammation or infection of the epididymis—the long coiled tube at the back of each testicle that stores and transports sperm. Epididymitis causes swelling and **pain** in the testicle. There are many causes of epididymitis, but the most common cause is a sexually transmitted bacterial infection.

Demographics

Epididymitis is the most common cause of pain in the scrotum of adult males. It occurs most frequently in sexually active men between the ages of 18 and 40. Epididymitis is the second most common cause of scrotal pain in adolescent males, but seldom occurs in those who are not sexually active since most cases are caused by **sexually transmitted infections** (STIs). Boys, older men, and homosexual men are more likely to have epididymitis caused by a non-sexually transmitted bacterial **urinary tract infection**. These are particularly common among members of the military who **exercise** for extended periods without emptying their bladders. They are also more common in males with anatomical abnormalities of the urinary tract or who have undergone surgery for urinary tract problems.

Description

Epididymitis most often stems from an STI or other infection in the urethra (the tube that drains urine from the bladder) or other parts of the urinary tract that has spread to the epididymis. In prepubescent boys epididymitis usually begins with a bladder or kidney infection that spreads to the epididymis. Acute epididymitis is usually associated with the most severe pain and swelling. It comes on quickly and subsides with treatment. Chronic epididymitis continues for more than six weeks after treatment begins or recurs frequently. If the testicle as well as the epididymis is inflamed, the condition is known as epididymo-orchitis.

Risk factors

High-risk sexual behaviors put males at risk for epididymitis caused by an STI. High-risk behaviors include multiple sexual partners, a sexual partner with an STI, or sex without a condom. A previous STI increases the risk for future STIs.

Risk factors for epididymitis caused by a non-sexually transmitted infection include:

- infection of the urinary tract, bladder, kidney, or prostate
- previous or chronic urinary tract or prostate infections
- other recent illness
- an uncircumcised penis
- an anatomical abnormality of the urinary tract, such as narrowing of the urethra
- medical procedures that can introduce bacteria into the genitourinary tract, including surgery or urinary catheterization
- prostate enlargement

Risk factors for epididymitis in boys include:

- painful urination
- a history of urinary tract infections
- abnormal bladder function
- abnormalities of the genitals and/or urinary tract

Causes and symptoms

The most common causes of epididymitis among sexually active males under age 35 are the bacteria *Chlamydia trachomatis* and *Neisseria gonorrhoeae*, the causative organisms of the STIs chlamydia and **gonorrhea**, respectively. These infections begin in the urethra and spread to the testicle. The most common cause of epididymitis in prepubescent boys, homosexual men, and older men is a urinary tract infection that spreads to the testicle. Such infections are most often caused by *Escherichia coli* (*E. coli*). Other bacteria, such as *Ureaplasma*, can also cause epididymitis. In prepubescent boys epididymitis is usually associated

WWW.BOOKBAZ.IR

KEY TERMS

Acute—Sharp or severe, reaching a crisis rapidly.

Catheter—A hollow flexible tube that is inserted into a body cavity, duct, or vessel for the passage of fluids.

Chronic—Of long duration or frequent recurrence.

Epididymis—The duct between the testis and the vas deferens for the passage of sperm.

Prostate—The walnut–shaped gland that surrounds the urethra at the neck of the bladder in males and supplies fluid for semen.

Sexually transmitted infection (STI)—An infectious disease that is transmitted through sexual activity.

Testicle, testis—One of the pair of male sex glands, located in the scrotum, which produces hormones and sperm.

Urethra—The opening at the end of the penis that drains urine from the bladder.

Vas deferens—The duct that stores sperm and carries it from the epididymis to the ejaculatory duct.

with a congenital abnormality that predisposes them to urinary tract infections.

Other causes of epididymitis include:

- bacterial infection of the prostate (prostatitis)
- infection with *Mycobacterium tuberculosis*, which causes tuberculosis (TB)
- rarely, a fungal infection
- injury or infection of the scrotum
- irritation from urine that has accumulated in the vas deferens (the sperm duct leading from the epididymitis)
- urine that has flowed backwards into the epididymitis, as can occur with heavy lifting or strain
- an enlarged prostate that obstructs the bladder outlet
- partial blockage of the urethra
- urethral catheterization
- the heart arrhythmia medication amiodarone

The cause of chronic epididymitis is sometimes difficult or impossible to determine.

Epididymitis is characterized by testicular pain. Usually only one testicle is affected. The pain of acute epididymitis generally develops gradually over several hours or days and is accompanied by a sudden redness and swelling of the testicle. The symptoms of chronic epididymitis generally come on much more gradually. The affected testicle is hard and sore and the other testicle may feel tender. Enlarged lymph nodes in the groin can cause pain in the scrotum, which intensifies throughout the day and may become so severe that it is impossible to walk normally. Bowel movements can increase the pain. Other symptoms of epididymitis include:

- chills
- a low-grade fever
- acute urethritis or inflammation of the urethra
- painful urination
- urgent or frequent need to urinate
- painful intercourse and/or ejaculation
- possibly a discharge from the urethra and blood in the semen
- a lump on the testicle
- pain or discomfort in the lower abdominal or pelvic region

Diagnosis

Examination

Diagnosis of epididymitis includes a medical history, sexual history, and a **physical examination**. The patient will be examined for enlarged lymph nodes in the groin, an enlarged testicle, tenderness in the area of the testicle where the epididymis attaches, and discharge from the penis. A **rectal examination** may reveal prostate tenderness or enlargement. Epididymitis may require consultation with a urologist.

Tests

Initial tests involve screening for an STI or other infection:

- urinalysis to check for the presence of bacteria and white blood cells, possibly including urine from an initial stream, mid-stream, and after a prostate massage
- urine cultures to identify the organism responsible for an infection
- tests of any discharge from the urethra and prostate gland
- a white blood cell count, which is usually elevated in the presence of infection

Procedures

Ultrasound or a nuclear scan of the testicles can reveal an enlarged epididymis and rule out conditions such as twisting of the spermatic cord (**testicular torsion**) or a testicular tumor. A nuclear scan involves injecting trace amounts of a radioactive material and using a special camera to detect areas of increased blood flow, indicating epididymitis, or decreased blood flow, indicating torsion.

Treatment

Traditional

Epididymitis is generally treated with **antibiotics** to rid the body of infection. If a pocket of pus (an **abscess**) has formed, it may need to be surgically drained. In some instances part or all of the epididymis or even the testicle must be surgically removed. An epididymectomy removes the inflamed section of the epididymis through a small incision in the scrotum. A **vasectomy** prevents fluid and sperm from passing through the epididymis. Surgery is usually performed only in cases of severe chronic epididymitis, on elderly patients undergoing prostate surgery, or when the epididymitis is caused by an underlying physical defect. Tuberculous epididymitis often requires surgical removal of a testicle.

Drugs

Epididymitis caused by an STI or other bacterial infection is treated with antibiotics, usually for at least two weeks. Sexual partners must also be treated for an STI. The antibiotics must be taken exactly as prescribed, even if the symptoms disappear before the course of antibiotics is completed.

If a second course of treatment does not completely eradicate symptoms, long-term anti-inflammatory therapy may be required.

Tuberculous epididymitis is treated with anti-tuberculosis medications.

Over-the-counter nonsteroidal anti-inflammatory drugs (NSAIDs), such as ibuprofen or naproxen, are used to reduce inflammation and relieve pain.

For severe pain a local anesthetic such as lidocaine (Xylocaine) may be injected directly into the spermatic cord.

Epididymitis caused by amiodarone is treated by temporarily discontinuing the drug or reducing the dosage.

Alternatives

Although antibiotics are required to treat infections that cause epididymitis, alternative therapies can reduce inflammation and promote healing. **Fasting** is recommended for some patients, since digestion slows down the body's healing mechanisms. A water fast may be preferred, but if this is not possible, a fruit- and vegetable-juice fast or a light diet of fresh fruits and vegetables is recommended.

Traditional Chinese medicine prescribes herbal formulas designed for individuals and their particular symptoms. Herbs for treating epididymitis that are toxic and should be used only under the direct supervision of an experienced herbalist include:

- philodendron (Huang Bai) for inflammation in the lower torso
- pulsatilla for pain and swelling, especially in the genitals
- podophyllum

Other herbs for treating epididymitis include:

- echinacea
- horsetail
- saw palmetto berries
- cranberry extract
- chimaphilla

Other alternative treatments for epididymitis include:

- homeopathic remedies prescribed specifically for the individual by a homeopathic practitioner
- acupuncture, which may help prevent another infection
- aromatherapy, such as a hot sitz bath with drops of juniper berry or sandalwood to relieve symptoms of infection
- chiropractic manipulation to strengthen bladder muscles by adjusting the joints and bones in the pelvic area to help control infection

Home remedies

Epididymitis usually requires at least one or two days of bed rest until symptoms subside. Scrotal elevation is considered to be very important: the patient lies with a folded towel under the scrotum to position it above the level of the heart. This improves blood flow out of the testicle, reduces swelling and pain, and promotes healing. Other self-care for epididymitis includes:

WWW.BOOKBAZ.IR

- applying scrotal cold packs, which should be wrapped in a towel and removed every 30 minutes to avoid skin damage
- hydrotherapy—sitting in water as hot as can be tolerated for 15–30 minutes once or twice a day, to alleviate discomfort and speed recovery
- drinking plenty of fluids to treat infection
- avoiding caffeine
- using stool softeners or eating plenty of fruit, nuts, whole-grain cereals, and other foods with laxative properties to prevent constipation
- avoiding strenuous activities until symptoms disappear
- wearing an athletic supporter when resuming normal activities
- avoiding sexual activity until symptoms have disappeared and possibly for as long as one month afterward

Prognosis

Symptoms of epididymitis caused by an STI or other bacterial infection usually improve within a few days of beginning antibiotic treatment. However, complete healing may take weeks or even months. Chronic epididymitis may require years of medication and ongoing treatment. Even an epididymectomy may not relieve scrotal pain.

Untreated epididymitis can lead to serious complications including:

- abscesses
- chronic epididymitis
- shrinkage (atrophy) of the affected testicle
- rarely, reduced fertility or infertility

Prevention

Many cases of epididymitis can be prevented through monogamy, the use of **condoms**, and avoiding sex with a partner who is infected with an STI. If the epididymitis is caused by an STI, all sexual partners must be treated to prevent re-infection. Drinking plenty of fluids to increase urine flow helps prevent urine retention, which can lead to infection and epididymitis.

Epidural abscess *see* **Central nervous system infections**

Epidural anesthetic *see* **Anesthesia, local**

Epidural therapy

Definition

An epidural is a local (regional) anesthetic delivered through a catheter (small tube) into a vacant space outside the spinal cord, called the epidural space.

The drugs commonly used in epidural **anesthesia** are bupivacaine (Marcaine, Sensorcaine), chloroprocaine (Nesacaine), and lidocaine (Xylocaine). The solutions of anesthetic should be preservative-free.

Purpose

The anesthetic agents that are infused through the small catheter block spinal nerve roots in the epidural space and the sympathetic nerve fibers adjacent to them. Epidural anesthesia can block most of the **pain**

KEY TERMS

Analgesia—A medication that decreases the awareness of pain.

Anesthesia—Loss of sensation through the administration of substances that block the transmission of nerve impulses signaling the feeling of pain and pressure.

Regional anesthesia—Blocking of specific nerve pathways through the injection of an anesthetic agent into a specific area of the body.

of labor and birth for vaginal and surgical deliveries. Epidural analgesia is also used after cesarean sections to help control postoperative pain. More than 50% of women giving birth at hospitals use epidural anesthesia.

Description

Epidural anesthesia, because it virtually blocks all pain of labor and birth, is particularly helpful to women with underlying medical problems such as pregnancy-induced **hypertension**, **heart disease**, and pulmonary disease. Epidural anesthesia for labor is usually initiated at the woman's request, provided that the labor is progressing well, or if the mother feels severe pain during early labor.

It is important not to place a woman flat on her back after she has an epidural because the supine position can bring on **hypotension**. If a woman's blood pressure does drop, then the proper treatment is to turn her on her side, administer oxygen, increase the flow of intravenous fluids, and possibly administer ephedrine if the hypotension is severe. Very rarely, convulsions can result from severe reactions. Seizure activity would be treated with short-acting **barbiturates** or diazepam (Valium).

Precautions

The primary problem associated with receiving epidural anesthesia is low blood pressure, otherwise known as hypotension, because of the blocking of sympathetic fibers in the epidural space. The decreased peripheral resistance that results in the circulatory system causes dilation of peripheral blood vessels. Fluid collects in the peripheral vasculature (vessels), simulating a condition that the body interprets as low fluid volume. A simple measure that prevents most hypotension is the infusion of 500–1000 cc of fluid intravenously into the patient prior to the procedure. Ringer's lactate is preferable to a solution containing dextrose because the elevated maternal glucose that accompanies the rapid infusion of solutions containing dextrose can result in hyperglycemia in the newborn with rebound **hypoglycemia**.

Preparation

To prepare for the administration of epidural anesthesia, the woman should have the procedure explained fully and sign required consent forms. An intravenous line is inserted, if not already in place. She is positioned on her side or in a sitting position and connected to a blood pressure monitoring device. The nurse/assistant has the following equipment available: oxygen, epidural insertion equipment, fetal monitor, and additional intravenous fluid.

The health care provider cleans the area with an antiseptic solution, injects a local anesthetic to create a small wheal at the L 3–4 area (between the third and fourth lumbar vertebrae), and inserts a needle into the epidural space. Once it is ascertained that the needle is in the correct place, a polyethylene catheter is threaded through the needle. The needle is removed and a test dose of the anesthetic agent is administered. The catheter is taped in place along the patient's back with the end over her shoulder for easy retrieval when further doses are required.

If the patient responds well to the test dose, a complete dose is administered. Pain relief should come up to the level of the umbilicus. The epidural anesthesia lasts approximately 40 minutes to two hours, or longer as required. If necessary, additional doses of anesthetic, or top-up, are injected through the catheter or by continuous infusion on a special pump.

Epidural anesthesia can be given in labor in a "segmented" manner. In this instance, the laboring woman receives a small dose of anesthesia so that the perineal muscles do not fully relax. The baby's head is more apt to undergo internal rotation when the perineal muscles are not too loose, thus facilitating delivery. At the time of delivery, an additional dose can be administered for perineal relief.

Women who have cesarean deliveries may have additional medication injected into the epidural space to control intra-operative pain. Medications generally used are **narcotics** such as fentanyl or morphine (Duramorph). Side effects include severe **itching**, nausea, and **vomiting**. Treatment of these side effects with the appropriate medication can be helpful. Despite these problems, epidural analgesia is an effective

WWW.BOOKBAZ.IR

method to relieve pain after cesarean delivery, allowing the woman to move easily and speed recovery.

Local anesthetics are generally safe when administered by the epidural route. There is a low frequency of allergic reaction to the drug. Most often the drug causes a mild skin reaction, but in more severe cases can cause breathing difficulty and an asthma-like reaction. A burning sensation at the site of injection may occur, sometimes with swelling and skin irritation. Other adverse reactions may occur if the epidural anesthetic is not properly administered.

Aftercare

It is important to carefully monitor vital signs after the administration of epidural anesthesia. Hypotension can result in fetal death and can also have grave consequences for the mother. The nurse should monitor the patient constantly and use a continuous blood pressure machine to obtain regular blood pressure readings for 20–30 minutes after each administration of anesthesia. The systolic blood pressure should not fall below 100 mm Hg or be 20 mm Hg less than a baseline systolic blood pressure for a hypertensive patient.

It is important to remind the woman to empty her bladder at least every two hours. With epidural anesthesia, there is loss of sensation of the need to void. Sometimes, an overfull bladder can block the descent of the baby's head. A catheter can be inserted into the bladder to drain the urine. The nurse needs to closely monitor intake and output and assess the bladder for signs of distension.

Risks

Side effects and complications are rare, but sometimes the patient will experience a "spinal headache" due to leakage of cerebrospinal fluid (CSF).

When a woman receives epidural anesthesia for labor pains, at times the labor can be prolonged because of excessive relaxation of the muscles. Also, the baby's head may not rotate—especially if it is in the occiput posterior position (the back of the head is facing toward the woman's back). The woman may not have the sensation that results in the desire to push during contractions when she is fully dilated. These complications may result in an increased incidence of births with the use of vacuum extraction, forceps, or even cesarean deliveries. Administering a Pitocin (oxytocin) drip intravenously can counter this problem. Pitocin is a medication that causes the uterus to contract. Allowing the epidural to wear off in the second stage of labor when the woman is pushing may avoid this problem, but the return of the labor pains may be overwhelming to the woman.

Occasionally, slow absorption of the medication from the epidural space into the circulation can result in toxic reactions evident by decreased level of consciousness, slurred speech, loss of coordination, drowsiness, nervousness, and **anxiety**. The health care provider should look out for these signs, and also report any elevation in temperature before a top-up dose is administered.

Results

Epidural anesthesia is a safe and effective method of giving pain relief to women during labor and delivery. It also can be used for cesarean births. It is believed that very little of the anesthetic is absorbed throughout the body (systemically), therefore epidural anesthesia is ideal because it does not pass the medication into the fetal circulation.

Epiglottitis

Definition

Epiglottitis is an infection of the epiglottis, which can lead to severe airway obstruction.

Description

When air is inhaled (inspired), it passes through the nose and the nasopharynx or through the mouth and the oropharynx. These are both connected to the larynx, a tube made of cartilage. The air continues down the larynx to the trachea. The trachea then splits into two branches, the left and right bronchi (bronchial tubes). These bronchi branch into smaller air tubes that run within the lungs, leading to the small air sacs of the lungs (alveoli).

Either food, liquid, or air may be taken in through the mouth. While air goes into the larynx and the respiratory system, food and liquid are directed into the tube leading to the stomach, the esophagus. Because food or liquid in the bronchial tubes or lungs could cause a blockage or lead to an infection, the airway is protected. The epiglottis is a leaf-like piece of cartilage extending upwards from the larynx. The epiglottis can close down over the larynx when someone is eating or drinking, preventing these food and liquids from entering the airway.

Epiglottitis is an infection and inflammation of the epiglottis. Because the epiglottis may swell considerably, there is a danger that the airway will be blocked off by the very structure designed to protect it. Air is then unable to reach the lungs. Without intervention, epiglottitis has the potential to be fatal.

Epiglottitis is primarily a disease of two to seven-year-old children, although older children and adults can also contract it. Boys are twice as likely as girls to develop this infection. Because epiglottitis involves swelling and infection of tissues, which are all located at or above the level of the epiglottis, it is sometimes referred to as supraglottitis (*supra,* meaning above). About 25% of all children with this infection also have **pneumonia**.

Causes and symptoms

The most common cause of epiglottitis is infection with the bacteria called *Haemophilus influenzae type b*. Other types of bacteria are also occasionally responsible for this infection, including some types of *Streptococcus* bacteria and the bacteria responsible for causing **diphtheria**.

A patient with epiglottitis typically experiences a sudden **fever**, and begins having severe throat and neck **pain**. Because the swollen epiglottis interferes significantly with air movement, every breath creates a loud, harsh, high-pitched sound referred to as **stridor**. Because the vocal cords are located in the larynx just below the area of the epiglottis, the swollen epiglottis makes the patient's voice sound muffled and strained. Swallowing becomes difficult, and the patient may drool. The patient often leans forward and juts out his or her jaw, while struggling for breath.

Epiglottitis strikes suddenly and progresses quickly. A child may begin complaining of a **sore throat**, and within a few hours have extremely severe airway obstruction.

Diagnosis

Diagnosis begins with a high level of suspicion that a quickly progressing illness with fever, sore throat, and airway obstruction is very likely to be epiglottitis. If epiglottitis is suspected, no efforts should be made to look at the throat, or to swab the throat in order to obtain a culture for identification of the causative organism. These maneuvers may cause the larynx to go into spasm (laryngospasm), completely closing the airway. These procedures should only be performed in a fully-equipped operating room, so that if laryngospasm occurs, a breathing tube can be immediately placed in order to keep the airway open.

An instrument called a laryngoscope is often used in the operating room to view the epiglottis, which will appear cherry-red and quite swollen. An x-ray picture taken from the side of the neck should also be obtained. The swollen epiglottis has a characteristic appearance, called the "thumb sign."

Treatment

Treatment almost always involves the immediate establishment of an artificial airway: inserting a breathing tube into the throat (intubation); or making a tiny opening toward the base of the neck and putting a breathing tube into the trachea (tracheostomy). Because the patient's apparent level of distress may not match the actual severity of the situation, and because the disease's progression can be surprisingly rapid, it is preferable to go ahead and place the artificial airway, rather than adopting a wait-and-see approach.

Because epiglottitis is caused by a bacteria, **antibiotics** such as cefotaxime, ceftriaxone, or ampicillin with sulbactam should be given through a needle

WWW.BOOKBAZ.IR

KEY TERMS

Epiglottis—A leaf-like piece of cartilage extending upwards from the larynx, which can close like a lid over the trachea to prevent the airway from receiving any food or liquid being swallowed.

Extubation—Removal of a breathing tube.

Intubation—Putting a breathing tube into the airway.

Laryngospasm—Spasm of the larynx.

Larynx—The part of the airway lying between the pharynx and the trachea.

Nasopharynx—The part of the airway into which the nose leads.

Oropharynx—The part of the airway into which the mouth leads.

Supraglottitis—Another term for epiglottitis.

Trachea—The part of the airway that leads into the bronchial tubes.

Tracheostomy—A procedure in which a small opening is made in the neck and into the trachea. A breathing tube is then placed through this opening.

placed in a vein (intravenously). This prevents the bacteria that are circulating throughout the bloodstream from causing infection elsewhere in the body.

Prognosis

With treatment (including the establishment of an artificial airway), only about 1% of children with epiglottitis die. Without the artificial airway, this figure jumps to 6%. Most patients recover form the infection, and can have the breathing tube removed (extubation) within a few days.

Prevention

Prevention involves the use of a vaccine against *H. influenzae type b* (called the Hib vaccine). It is given to babies at two, four, six, and 15 months. Use of this vaccine has made epiglottitis a very rare occurrence.

Rosalyn Carson-DeWitt, MD

Epilepsy

Definition

Epilepsy is a chronic (persistent) disorder of the nervous system. The primary symptoms of this disease are periodic or recurring seizures that are triggered by sudden episodes of abnormal electrical activity in the brain. The term "seizure" refers to any unusual body functions or activities that are under the control of the nervous system.

Demographics

Epilepsy affects about 1% of the population. Approximately 2.3 million Americans and 40 million people throughout the world have epilepsy. It is the second most common neurological disorder. According to the Epilepsy Foundation, about 30% of the 200,000 new cases reported every year begin in childhood, particularly in early childhood and around the time of adolescence. Another period of relatively high incidence is in people over the age of 65.

Description

The word epilepsy is derived from the Greek term for seizure. Seizures can involve a combination of sensations, muscle contractions, and other abnormal body functions. Seizures may appear spontaneously—without any apparent cause—or can be triggered by a specific type of stimulus such as a flashing light. Specific cases of epilepsy may result from known causes, such as brain injury, or may have no apparent cause (referred to as idiopathic epilepsy). Idiopathic epilepsy may be initiated by a combination of genetic and environmental factors.

An epileptic seizure involves a transient (temporary) episode of abnormal electrical activity in the brain. During a seizure, many nerve cells within a specific region of the brain may begin to fire at the same time. This activity may then spread out over other parts of the brain. In addition to abnormal physical symptoms, seizures can bring on emotions ranging from fear, anger, and rage, to joy or happiness. During a seizure, patients may experience disorientation, spontaneous sensations of sounds, smells, visions, and distorted visual perception—such as misshapen objects and places.

Epilepsy can be caused by some event or condition that results in damage to the brain such as strokes, tumors, abscesses, **trauma** (physical injury), or infections such as **meningitis**. Epilepsy can also be triggered by inherited (genetic) factors or some form of injury or

trauma at birth. Epilepsy cases that seem to have no readily identifiable cause are referred to as "idiopathic" cases in medical terminology. Symptoms of this disease can appear at any age. Seizures can damage and destroy brain cells and scar tissue can develop in the section of brain tissue where seizures originate.

There are many forms of epileptic seizures. The parts of the body that are affected by a seizure and the distinctive characteristics, duration and severity of the symptoms can distinguish each type of epilepsy. Patients can experience more than one type of seizure. The nature of the symptoms depends on where in the brain the seizure originated and how much of the brain is involved. Seizures can be classified as either "generalized" or "partial." Partial seizures involve abnormal activity in a specific region of the brain.

Generalized (also called tonic–clonic) seizures last about two minutes and are the result of abnormal electrical activity that spreads out over both sides or hemispheres of the brain. They were formerly referred to as grand mal seizures. The patient will usually lose consciousness and fall during the episode. The term "tonic" refers to the first phase of a generalized seizure in which the body muscles become taunt or stiff. This is followed by strong, rhythmic muscular contractions (convulsions) of the "clonic" phase. Sometimes a patient's breathing may be hampered by a brief stoppage of the respiratory muscles, causing the skin to develop a bluish tinge due to lack of oxygen.

Epileptic seizures can also be classified as complex or simple. Complex seizures generally involve a loss of consciousness, whereas simple seizures do not. Simple partial seizures can begin as a localized (focal) seizure and then evolve into a secondary generalized episode in which the initial abnormal electrical activity spreads to involve other parts of the brain. Patients may actually remember the physical and psychological events that occur during a simple seizure, such as the types of movement, emotions, and sensations, but frequently are completely unaware of the event. Partial seizures are more common in adults.

An absence seizure (once called *petit mal*) typically results in brief periods of lack of awareness and some abnormal muscle movement. The patient generally remains conscious during the seizure episode, but may become absent–minded and unresponsive. They may also appear to be starring. Absence seizures last about 5–10 seconds.

How seizures affect a person's memory depends where in the brain seizures occur. Seizures can interfere with learning, storage, and retrieval of new information. For example, a form of epilepsy that produces seizures in the temporal lobe of the brain can cause a serious deterioration (loss) of memory function. Early treatment can help prevent or reduce **memory loss**.

In some forms of epilepsy, seizures can be triggered by a particular mental—or cognitive—activity. For example, the simple activity of reading aloud can trigger a seizure in patients with reading epilepsy. Symptoms include face **muscle spasms**. In medical terms, this type of epilepsy is referred to as idiopathic localization–related epilepsy. This means that seizures occur in one part of the brain (in this case, the temporal lobes) and that there is no apparent cause that brought on the disease.

Risk factors

Certain factors may increase the risk of epilepsy. The Mayo Clinic lists the following:

- Age: the onset of epilepsy is most common during early childhood and after age 65, but the condition can occur at any age.
- Sex: men are slightly more at risk of developing epilepsy than are women.
- Family history: a family history of epilepsy may increase the risk of developing a seizure disorder.
- Head injuries: head injuries are responsible for many cases of epilepsy.
- Stroke and other vascular diseases: these conditions can lead to brain damage that may trigger epilepsy.
- Brain infections: infections like meningitis, which causes an inflammation in the brain or spinal cord, can increase the risk of epilepsy.
- Prolonged seizures in childhood: high fevers in childhood can sometimes be associated with prolonged seizures and subsequent epilepsy later in life.

Causes and symptoms

Epilepsy has many causes that have an effect on the clinical presentation of symptoms. In order for epilepsy to occur, there must be an underlying physical problem in the brain. The problem can be so mild that a person can be perfectly normal aside from having seizures. The brain has roughly 50–100 billion neurons. Each neuron can have up to 10,000 contacts with neighboring neurons. Hence, trillions of connections exist. However, only a very small area of dysfunctional brain tissue is necessary to create a persistent generator of seizures and, hence, epilepsy. The following are potential causes of epilepsy:

- genetic and/or hereditary
- perinatal neurological insults
- trauma with brain injury

WWW.BOOKBAZ.IR

- stroke
- brain tumors
- infections such as meningitis and encephalitis
- multiple sclerosis
- idiopathic (unknown or genetic)

Any of these conditions has the potential for causing the brain or a portion of it to be dysfunctional and produce recurrent seizures. Regardless of the exact cause, epilepsy is a paroxysmal (sudden) condition. It involves the synchronous discharging of a population of neurons. This is an abnormal event that, depending on the location in the brain, will correspond to the particular symptoms of a seizure. The International League Against Epilepsy (ILAE) issued a classification of types of seizures. Individual seizure types are based on the clinical behavior (semiology) and electrophysiological characteristics as seen on an electroencephalogram (EEG). Generalized seizures included in the list include:

- tonic–clonic seizures (includes variations beginning with a clonic or myoclonic phase)
- clonic seizures, including without tonic features and with tonic features
- typical absence seizures
- atypical absence seizures
- myoclonic absence seizures
- tonic seizures
- spasms
- myoclonic seizures
- eyelid myoclonia, including without absences and with absences
- myoclonic atonic seizures
- negative myoclonus
- atonic seizures
- reflex seizures in generalized epilepsy syndromes

Partial (or focal) seizures included in the ILAE list are:

- focal sensory seizures with elementary sensory symptoms (e.g., occipital and parietal lobe seizures) and experiential sensory symptoms (e.g., temporo–parieto–occipital junction seizures)
- focal motor seizures with elementary clonic motor signs, asymmetrical tonic motor seizures (e.g., supplementary motor seizures), typical (temporal lobe) automatisms (e.g., mesial temporal lobe seizures), hyperkinetic automatisms, focal negative myoclonus, and inhibitory motor seizures
- gelastic seizures
- hemiclonic seizures
- secondarily generalized seizures
- reflex seizures in focal epilepsy syndromes

The International League Against Epilepsy has also issued the following classification of epilepsies and epileptic syndromes:

- benign familial neonatal seizures
- early myoclonic encephalopathy
- Ohtahara syndrome
- migrating partial seizures of infancy (syndrome in development)
- West syndrome
- benign myoclonic epilepsy in infancy
- benign familial and non–familial infantile seizures
- Dravet's syndrome
- HH syndrome
- myoclonic status in nonprogressive encephalopathies (syndrome in development)
- benign childhood epilepsy with centrotemporal spikes
- early onset benign childhood occipital epilepsy (Panayiotopoulos type)
- late–onset childhood occipital epilepsy (Gastaut type)
- epilepsy with myoclonic absences
- epilepsy with myoclonic–astatic seizures
- Lennox–Gastaut syndrome
- Landau–Kleffner syndrome (LKS)
- epilepsy with continuous spike–and–waves during slow–wave sleep (other than LKS)
- childhood absence epilepsy
- progressive myoclonus epilepsies
- idiopathic generalized epilepsies with variable phenotypes include juvenile absence epilepsy, juvenile myoclonic epilepsy, and epilepsy with generalized tonic–clonic seizures only
- reflex epilepsies
- idiopathic photosensitive occipital lobe epilepsy
- other visual sensitive epilepsies
- primary reading epilepsy
- startle epilepsy
- autosomal dominant nocturnal frontal lobe epilepsy
- familial temporal lobe epilepsies
- generalized epilepsies with febrile seizures plus (syndrome in development)
- familial focal epilepsy with variable foci (syndrome in development)
- symptomatic focal epilepsies
- limbic epilepsies

- mesial temporal lobe epilepsy with hippocampal sclerosis
- mesial temporal lobe epilepsy defined by specific etiologies
- neocortical epilepsies
- Rasmussen syndrome

Classifying epilepsy is used in the evaluation and management of patients with seizure disorders. The combination of seizure type(s), etiology (cause), age of onset, family history, and other medical or neurological conditions can help identify an epilepsy syndrome. Syndrome classification schemes are revised periodically as individual components of particular categories are better understood.

The term idiopathic refers to a cause that is unknown. Cryptogenic is a term that suggests that an underlying cause is suspected, but not yet fully understood. Symptomatic is a term that is applied to epilepsies that are a result of understood underlying pathologies.

The management and prognosis vary considerably among these differing syndromes. Epilepsies that have a genetic basis can be inherited or occur spontaneously. A detailed family history can often identify other family members who have had seizures. However, because seizures are common, it is possible to have more than one family member with epilepsy, though the causes may not be related. To say that a particular type of epilepsy is genetic does not mean that it is necessarily transmitted by heredity. Often, disorders can have a genetic cause, but may be spontaneously occurring in only one member of a family. In this case, there may simply be a random mutation in that particular person's genes.

Genetic factors contribute to about 40% of all epilepsy cases. Most of the generalized epilepsy syndromes and some of the partial epilepsy syndromes have an inherited component. Medical researchers suggest that at least 500 genes may somehow be involved in the development of various forms of epilepsy. It is believed that some of these genes can make people with epilepsy more susceptible or sensitive to environmental factors that initiate or start seizures. Only a few types of epilepsy are thought to be caused by just one type of gene.

Gene mutations can cause a variety of nervous system abnormalities that are associated with epilepsy. Different mutations may lead to abnormal brain development or progressive degeneration of brain tissue. Some gene mutations make nerve cells hyperexcitable. These abnormal nerve cells can trigger outbursts of abnormal patterns of electrical activity that can initiate an epileptic seizure.

Specific gene locations (called gene markers) have been linked to various forms of the disease, such as juvenile myoclonic epilepsy. However, researchers have discovered that some individuals who possess this gene do not develop symptoms of this disease. In some pairs of identical twins with this gene, one twin may appear normal while the other develops typical symptoms of epilepsy. Thus, genetic inheritance seems to be just one of many factors that influence the possibility of developing epilepsy symptoms.

Some genetic mutations may also reduce the effectiveness of antiepileptic medication. One of the major goals of epilepsy research is to determine how a patient's genetic makeup can influence their drug therapy.

With epilepsy, symptoms vary considerably depending on the type. The common link among the epilepsies is, of course, seizures. The different epilepsies can sometimes be associated with more than one seizure type. This is the case with Lennox–Gastaut syndrome.

The specific symptoms of epilepsy accordingly depend in part on the particular seizures that occur and other medical problems that may be associated. Seizures, themselves, can take on a variety of features. A simple sustained twitching of an extremity could be a partial seizure. If a seizure arises in the occipital lobes of the brain, then a visual experience can occur. Aura is a term often used to describe symptoms that a person may feel prior to the loss of consciousness of a seizure. However, auras are, themselves, small partial seizures that have not spread in the brain to involve consciousness. Smells, well–formed **hallucinations**, tingling sensations, or nausea have all occurred in auras. The particular sensation can be a clue as to the location in the brain where a seizure starts. Partial seizures can then spread to involve other areas of the brain and lead to an alteration of consciousness, and possibly convulsions. In certain epilepsy syndromes such as Lennox–Gastaut, there can be more than one type of seizure experienced, such as atonic, atypical absence, and tonic–axial seizures.

Diagnosis

Examination

The diagnosis of epilepsy is relatively straightforward: when people have two or more seizures, they are considered to have epilepsy. However, diagnosing the specific epilepsy syndrome is much more complex. The

WWW.BOOKBAZ.IR

KEY TERMS

Aura—A sensation of a cold breeze or bright light that precedes the onset of a seizure.

Automatisms—Movements during a seizure that are semi–purposeful but involuntary.

Clonic—Referring to clonus, rapid contractions and relaxations of a muscle.

Convulsion—Involuntary contractions of body muscles that accompany a seizure episode.

Gelastic seizures—Seizures manifesting with brief involuntary laughter.

Gray matter—The portion of the brain that contains neurons, as opposed to white matter, which contains nerve tracts.

Infantile spasms—Clusters of rapid jerks followed by stiffening or jackknife movements. Usually starts in the first year of life and stops by age 4.

Idiopathic—Of unknown origin.

Lesion—A defective or injured section or region of the brain (or other body organ).

Magnetic resonance imaging (MRI)—A technique that employs magnetic fields and radio waves to create detailed images of internal body structures and organs, including the brain.

Myoclonic—A rapid, involuntary muscle contraction, particularly near the eye.

Myoclonus—Jerking, involuntary movements of the arms and legs. These may occur normally during sleep.

Neuron—A unique type of cell found in the brain and body that is specialized to process and transmit information.

Partial seizure—A seizure that starts in one particular part of the brain. The abnormal electrical activity may remain confined to that area, or may spread to the entire brain. Also called a focal seizure.

Reflex seizure—Seizure brought on by specific sensory stimuli.

Seizure—Any unusual body functions or activity that is under the control of the nervous system.

Spike wave discharge—Characteristic abnormal wave pattern in the electroencephalogram that is a hallmark of an area that has the potential of generating a seizure.

first step in the evaluation process is to obtain a very detailed history of the illness, not only from the patient but from the family as well. In a child, this includes birth history, complications, if any, maternal history, and developmental milestones. At any age, other medical problems are also considered. Medications that have been taken or currently being prescribed are documented. Since seizures can impair consciousness, the patient may not be able to recall specifics. In these cases, family or friends that have witnessed the episodes can fill in the gaps about the particulars of the seizure. The description of the behaviors during a seizure helps to categorize the type of seizure and with the overall diagnosis.

A complete **physical examination** is performed, especially a **neurological exam**. Because seizures are an episodic disorder, abnormal neurological findings may not be present. Frequently, people with epilepsy have a normal exam. However, in some, there can be abnormal findings that can provide clues to the underlying cause of epilepsy. For example, if someone has had a **stroke** that subsequently caused seizures, then the neurological exam can be expected to reveal a focal neurological deficit such as weakness or language difficulties. In some children with seizures, there can be a variety of associated neurologic abnormalities such as intellectual disabilities (ID) and **cerebral palsy** that are themselves non–specific but indicate that the brain has suffered, at some point in development, an injury or malformation. Also, subtle findings on examination can lead to a diagnosis of tuberous sclerosis. This is an autosomal dominantly inherited disorder associated with infantile spasms in 25% of cases. On examination, patients have so–called ash–leaf spots and adenoma sebaceum on the skin. There can also be a variety of systemic abnormalities that involve the kidneys, retina, heart, and gums, depending on severity.

Tests

In the course of evaluating epilepsy, a number of tests are typically ordered. Usually, **magnetic resonance imaging** (MRI) of the brain is performed. This is a scan that can help to find causes of epilepsy such as tumors, strokes, trauma, and congenital malformations. While MRI can reveal incredible brain details, it cannot image the presence of abnormalities in the microscopic neuronal environment. Another test that is routinely ordered is an electroencephalogram (EEG).

Unlike the MRI scan, this can be considered a functional test of the brain. The EEG measures the electrical activity of the brain. Some seizure disorders or epilepsies have a characteristic EEG with particular abnormalities that can help in diagnosis. Blood tests are also frequently ordered to help screen for abnormalities that could be a factor in the cause of seizures. Occasionally, **genetic testing** is performed in those instances where a known genetic cause is suspected and can be tested. A major concern in the course of an evaluation of epilepsy is to identify the presence of life–threatening causes such as brain tumors, infections, and cerebrovascular disease.

Treatment

Traditional

Currently, no cure exists for epilepsy. However, a wide range of treatment programs are available that provide varying degrees of success in controlling the symptoms of epilepsy.

Drugs

Medication is the most effective and widely used treatment for the symptoms of epilepsy. Most medications work by interfering with or stopping the abnormal electrical activity in nerve cells that cause seizures. This form of treatment is generally referred to as anticonvulsant therapy. Medication is considered effective if the patient is free of seizures for at least one year.

As with any medication, individuals can have very different experiences with same drug. Consequently, it is difficult to predict the efficacy of treatment. A key concept of treatment is to first strive for monotherapy (or single drug therapy). This simplifies treatment and minimizes the chance of side effects. Sometimes, two or more drugs may be necessary to achieve satisfactory control of seizures. As with any treatment, potential side effects can be worse than the disease itself. Moreover, there is little point in controlling seizures if severe side effects limit quality of life. If a **seizure disorder** is characterized by mild, focal, or brief symptoms that do not interfere with routine activities, then aggressive treatments may not be advisable. Epilepsy medications do not cure epilepsy; the medications can only control the frequency and severity of seizures. A list of the most commonly used medications in the management of epilepsy includes:

- phenobarbital
- phenytoin (Dilantin, Phenytek)
- clonazepam (Klonipin)
- ethosuxamide (Zarontin)
- carbamazepine (Tegretol, Carbatrol)
- divalproex sodium (Depakote, Depakene)
- felbamate (Felbatol)
- gabapentin (Neurontin)
- lamotrigine (Lamictal)
- topiramate (Topamax)
- tiagabine (Gabatril)
- zonisamide (Zonegran)
- oxcarbazepine (Trileptal)
- leviteracetam (Keppra)

Anticonvulsants are powerful drugs that can produce a variety of side effects, including nausea, **fatigue**, **dizziness**, and weight change. They can also increase the risk of **birth defects**, especially involving the early stages of embryonic development of the nervous system if taken during **pregnancy**.

Doctors prefer to put their patients on just one type of anticonvulsant drug. Some patients, however, experience more effective relief from their epilepsy symptoms by taking a combination of two different but complementary forms of medication. The choice of medication depends on the type of seizure that affects a patient, the patient's medical history—including response to other drug therapies, their age, and gender. For example, the drug carbamazepine is one of the most effective medications and has little impact on important cognitive functions such as thinking, memory and learning.

Newer medications generally produce fewer side effects than their predecessors. Research into **gene therapy** may ultimately be the most effective form of epilepsy treatment, but is still in the very early stages.

Unfortunately, medication is ineffective for more than one-third of known cases of epilepsy. More than 30% of patients with epilepsy cannot maintain adequate control of their seizures. Some genetic mutations may reduce the effectiveness of antiepileptic medications.

Alternatives

Surgery is recommended for some patients for whom medication cannot effectively control the frequency or severity of their seizures. Surgery is a treatment option only in extreme cases where doctors can identify the specific site in the brain where seizures originate. The most promising candidates for surgery are those with a single lesion on the temporal, frontal, or occipital lobes of the brain.

Prior to surgery, the patient must complete extensive testing to determine the precise patterns of seizures and to locate their point of origin in the brain.

WWW.BOOKBAZ.IR

Patients spend extended stays in hospital during which their seizures are recorded on video and with the aid of EEGs. This machine records patterns of electrical activity in the brain using sensors (electrodes) attached to various parts of the body.

The surgical procedure involves the removal of a small part of brain tissue in the "suspected" region. The anterior temporal lobe and hippocampus are the most common areas in which tissue is removed. In some studies, more than 83% of patients become free of seizures following surgery. Ninety–seven percent show significant improvement in their condition.

Vagus Nerve Stimulation (VNS) is another form of treatment for some cases of epilepsy that are unresponsive (referred to as refractory epilepsy) to other forms of medical therapy. VNS may also be recommended for patients who cannot tolerate the side effects of medication. This procedure involves implanting a device that stimulates the Vagus nerve, located in the left side of the neck. In one study, this treatment reduced seizures by 78%.

A special dietary program is another treatment option for patients who are not good candidates for surgery or who have had little success with anticonvulsant medication. This form of treatment called the Ketogenic Diet can be effective for many types of epilepsy. It is most appropriate for young children whose parents can follow the rigid requirements of the diet. Older children and adults tend to have greater difficulty in sticking to the dietary rules for an extended period of time. The Ketogenic Diet is a stringent diet that is very high in fat, but low in proteins, carbohydrates, and calories. The excessive fat produces high levels of a substance called ketones (which the body makes when it breaks down fat for energy). Somehow these ketones help reduce the incidence of epileptic seizures. The success of this form of treatment varies. For some patients, the high fat diet is the best form of treatment. For others, the diet is less effective.

As of 2014, 299 open clinical trials for the study and treatment of epilepsy were being sponsored by the National Institutes of Health (NIH)and other agencies.

A few examples include:

- The effectiveness and safety of diazepam for patients with epilepsy who receive antiepileptic drugs. (NCT00319501)
- The role played by the brain chemical serotonin in seizures. (NCT00439387)
- The effectiveness and dose requirements of levetiracetam in subjects with newly diagnosed childhood absence epilepsy. (NCT00361010)
- The effectiveness of electrical brain stimulation to reduce epileptic seizures. (NCT00344877)
- The use of simultaneous EEG and functional magnetic resonance imaging (fMRI) to study the different brain regions involved in child absence seizures and how they are related to attention and cognition. (NCT00393666)
- The effectiveness and safety of seletracetam when it is used in addition to other anti–epileptic medications by patients with partial onset seizures. (NCT00422110)
- The evaluation of standard diagnostic tests and treatments for patients with epilepsy. (NCT00013845)
- The collection of brain tissue samples for research purposes from patients undergoing surgery to treat epilepsy. (NCT00025714)
- The use of functional magnetic resonance imaging (fMRI) and diffusion tensor imaging (DTI) to examine how the brain processes tasks involving language and emotion in normal volunteers and in patients with epilepsy. (NCT00081432)

Clinical trial information is constantly updated by NIH and the most recent information on epilepsy trials can be found at: http://clinicaltrials.gov.

Prognosis

The prognosis of epilepsy varies widely depending on the cause, severity, and patient's age. Even individuals with a similar diagnosis may have different experiences with treatment. For example, in benign epilepsy of childhood with centrotemporal spikes (also called benign rolandic epilepsy), the prognosis is excellent with nearly all children experiencing remission by their teens. With childhood absence epilepsy, the prognosis is variable. In this case, the absence seizures become less frequent with time, but almost half of patients may eventually develop generalized tonic–clonic seizures. Overall, the seizures are responsive to an appropriate anticonvulsant. On the other hand, the seizures in Lennox–Gastaut syndrome are very difficult to control. In this case, the ketogenic diet can help. In seizures that begin in adulthood, one can expect that medications will control seizures in up to 60–70% of cases. However, in some of the more than 30% of medically intractable cases, epilepsy surgery can improve or even cure the problem.

Overall, most patients have a good chance of controlling seizures with the available treatment options. The goal of treatment is complete cessation of seizures since a mere reduction in seizure frequency and/or severity may continue to limit patients' quality of life: for instance, they may not be able to drive, sustain employment, or be productive in school.

Prevention

Head injuries are associated with many epilepsy cases. The risk can be reduced by always wearing a seat belt while riding in a car and by wearing a helmet while bicycling, skiing, riding a motorcycle or engaging in other activities with a high risk of **head injury**. **Vascular disease** may also lead to epilepsy. Limiting alcohol intake, avoiding cigarettes, eating a healthy diet and exercising regularly can reduce the risk for these diseases.

Episiotomy

Definition

An episiotomy is a surgical incision made in the perineum, the area between the vagina and anus. Episiotomies are done during the second stage of labor to expand the opening of the vagina to prevent tearing of the area during the delivery of the baby.

Purpose

An episiotomy is usually done during the birthing process in order to deliver a baby without tearing the perineum and surrounding tissue. Reasons for an episiotomy might include:

- There is evidence of maternal or fetal distress (e.g., no time to allow perineum to stretch).
- The baby is premature or in a breech position, and his/her head could be damaged by a tight perineum.
- The baby is too large to be delivered without causing extensive tearing.
- The baby's delivery is being assisted by forceps.
- The mother is too tired or unable to push.
- There is existing trauma to the perineum.

Some experts believe that an episiotomy speeds up the birthing process, making it easier for the baby to be delivered. Speed can be important if there is any sign of distress that may harm the mother or baby. Because tissues in this area may tear during the delivery, another reason for performing an episiotomy is that a clean incision is easier to repair than a jagged tear and may heal faster. Although episiotomies are sometimes described as protecting the pelvic muscles and possibly preventing future problems with **urinary incontinence**, it is not clear that the procedure actually helps.

Demographics

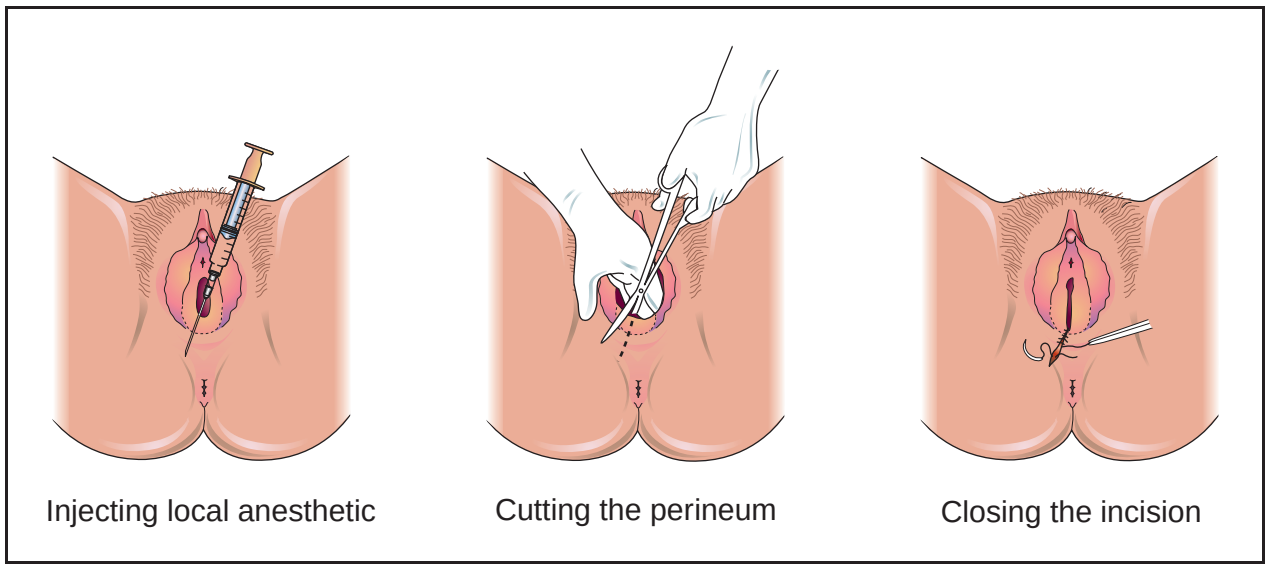
About 33% of all American women undergo episiotomy during labor and delivery. While this represents a dramatic drop from the 1983 rate of 69.4%, there are many experts who still believe that this represents too high a number. Episiotomy rates were higher among white women (32.1%) than African American women (11.2%). Similar differences have been reported in other obstetric procedures (e.g., **cesarean section** and epidural use).

Episiotomy rates differ according to care provider—patients of midwives have lower rates than patients of medical doctors. One study comparing perineal outcomes for women being cared for by midwives or medical doctors found the episiotomy rate among midwives at 25% and 40% among medical doctors. Younger doctors are also less likely to perform an episiotomy than older doctors; one study found the rate of episiotomies performed by residents to be 17%, while the rate among doctors in private practice was 66%.

Description

An episiotomy is a surgical incision, usually made with sterile scissors, in the perineum as the baby's head is being delivered. This procedure may be used if the tissue around the vaginal opening begins to tear or does not seem to be stretching enough to allow the baby to be delivered.

An episiotomy is performed by the health care provider attending to a woman's labor and delivery, typically an obstetrician/gynecologist or midwife. An obstetrician/gynecologist is a medical doctor who has completed specialized training in the areas of women's general health, pregnancy, labor and **childbirth**, prenatal testing, and genetics. A midwife is a person who has been trained to provide care, support, and supervision to women in all stages of pregnancy, labor, delivery, and the postpartum period. The procedure



An episiotomy is a surgical incision made in the perineum, the area of tissue between the vaginal opening and the anus, during the birthing process. This procedure may be used if the tissue around the vaginal opening begins to tear or is not stretching enough to allow the baby to be delivered vaginally. In the United States, the rate of episiotomies being performed is estimated at 65–95%. *(Illustration by Electronic Illustrators Group. © Cengage Learning®.)*

is performed at the site of labor and delivery, most often a hospital or birth center.

In most cases, the physician makes a midline incision along a straight line from the lowest edge of the vaginal opening toward the anus. In other cases, the episiotomy is performed by making a diagonal incision across the midline between the vagina and anus (called a mediolateral incision). This method is used much less often, may be more painful, and may require more healing time than the midline incision. After the baby is delivered through the extended vaginal opening, the incision is closed with stitches. A local anesthetic may be applied or injected to numb the area before it is sewn up (sutured).

Episiotomies are classified according to the depth of the incision:

- A first-degree episiotomy cuts through skin only (vaginal/perineal).
- A second-degree episiotomy involves skin and muscle and extends midway between the vagina and the anus.
- A third-degree episiotomy cuts through skin, muscle, and the rectal sphincter.
- A fourth-degree episiotomy extends through the rectum and cuts through skin, muscle, the rectal sphincter, and anal wall.

Preparation

Although there are some reasons for anticipating an episiotomy before labor has begun (e.g., breech presentation of the baby), the decision to perform an episiotomy is generally not made until the second stage of labor, when delivery of the baby is imminent.

Aftercare

The area of the episiotomy may be uncomfortable or even painful for several days. Several practices can relieve some of the **pain**. Cold packs can be applied to the perineal area to reduce swelling and discomfort. Use of a **sitz bath** can ease the discomfort. This unit circulates warm water over the area. A squirt bottle with water can be used to clean the area after urination or defecation rather than wiping with tissue. Also, the area should be patted dry rather than wiped. Cleansing pads soaked in witch hazel (such as the brand Tucks) are very effective for soothing and cleaning the perineum.

Risks

Several side effects of episiotomy have been reported, including infection (in 0.3% of cases), increased pain, increased bleeding, prolonged healing time, and increased discomfort once sexual intercourse is resumed. There is also the risk that the incision will be deeper or longer than is necessary to permit the birth of the infant. An incision that is too long or deep may extend into the rectum, causing more bleeding and an increased risk of infection. Additional

WWW.BOOKBAZ.IR

KEY TERMS

Kegel exercises—A series of contractions and relaxations of the muscles in the perineal area. These exercises are thought to strengthen the pelvic floor and may help prevent urinary incontinence in women.

Perineum—The area between the opening of the vagina and the anus in a woman, or the area between the scrotum and the anus in a man.

Sitz bath—A shallow tub or bowl, sometimes mounted above a toilet, that allows the perineum and buttocks to be immersed in circulating water.

Urinary incontinence—Inability to prevent the leakage or discharge of urine. It becomes more common as people age, and is more common in women who have given birth to more than one child.

tearing or tissue damage may occur beyond the episiotomy itself.

Studies have found that the rates of urinary/fecal incontinence, postpartum perineal pain, and **sexual dysfunction** are generally the same between women who have had an episiotomy and those who had a spontaneous tear of the perineum. There does appear to be a higher risk of more extensive perineal trauma when an episiotomy is performed (20.9% experienced third- or fourth-degree lacerations) than when it is not (3.1% experienced major perineal damage).

Results

In a normal and well-managed delivery, an episiotomy may be avoided altogether. If an episiotomy is considered necessary, a simple midline incision will be made to extend the vaginal opening without additional tearing or extensive **trauma** to the perineal area. Although there may be some pain associated with the healing of the incision, relief can usually be provided with mild pain relievers and supportive measures, such as the application of cold packs.

Alternatives

It may be possible to avoid the need for an episiotomy. Pregnant women may want to talk with their care providers about the use of episiotomy during the delivery. Kegel exercises are often recommended during the **pregnancy** to help strengthen the pelvic floor muscles. Prenatal perineal massage may help to stretch and relax the tissue around the vaginal opening. During the delivery process, warm compresses can be applied to the area along with the use of perineal massage. Coaching and support are also important during the delivery process. Slowed, spontaneous pushing during the second stage of labor (when the mother gets the urge to push) may allow the tissues to stretch rather than tear. Also, an upright birthing position (rather than one where the mother is lying down) may decrease the need for an episiotomy.

Epstein-Barr virus

Definition

Epstein-Barr virus, or EBV, is the name given to a member of the herpesvirus family that is associated with a variety of illnesses—from **infectious mononucleosis** (IM) and **multiple sclerosis** to nasopharyngeal cancer and Burkitt's lymphoma. EBV is also known as human herpesvirus 4 or HHV-4. It is named for Anthony Epstein and Yvonne Barr, who identified the virus in 1964 in tissue samples sent to them from Uganda by Denis Burkitt (1911–1993), for whom Burkitt's lymphoma was named.

Demographics

EBV occurs in nearly all regions of the world, and is considered among the most common infectious viruses known to humankind. It is likely that its genetic diversity is greater than was thought when it was first identified. In the United States, the Center for Disease Control (CDC) estimates that 95% of adult Americans between the ages of 35 and 40 years have been infected with EBV, but it is less prevalent in children and teenagers. This pattern of infecting adults more than children persists throughout other prosperous Western countries, but does not hold true in underdeveloped regions such as Africa and Asia. In Africa, most children have been infected by EBV by the age of three years.

About 10% of cancers of the stomach are associated with EBV. The reason for this association is not known as of 2009.

Nasopharyngeal cancer is uncommon in the West but more prevalent in the Far East. It affects three times as many men as women, and usually occurs in adults between the ages of 40 and 50 years. This type of cancer is diagnosed in fewer than 1 in every 100,000 Caucasians but in 10–53 persons per 100,000 in mainland China, Taiwan, Hong Kong, and Malaysia. It also occurs more frequently in Eskimos in Greenland and Alaska, and in Tunisians, with about 20 cases per 100,000 people per year. The prevalence rate for adults of Asian descent in the United States is 3–4.2 cases per 100,000 persons per year. Nasopharyngeal cancer accounts for less than 1% of malignancies in children. It affects 1 in every 100,000 children in North America and Europe each year, but between 8 and 25 of every 100,000 children in Asia.

Description

Herpesviruses have long been known. The name actually comes from the Greek adjective *herpestes*, which means creeping. Many herpesvirus species appear to establish a lifelong presence in the human body, remaining dormant for long periods and becoming active for some, often inexplicable, reason. EBV is only one of several members of the Herpesvirus family that have similar traits. Others include varicella zoster virus—the cause of both **chickenpox** and shingles—and the herpes simplex virus responsible for both **cold sores** and **genital herpes**. EBV is usually transmitted through saliva but not blood, and is not normally an airborne infection.

Individuals with EBV infections typically show some elevation in the **white blood cell count** and a noticeable increase in lymphocytes—white blood cells associated with the immune response of the body. IM is a time-limited infection that usually lasts from one to two months. Symptoms include **fever**, malaise, **sore throat**, **swollen glands** and (sometimes) swollen spleen and/or liver.

EBV infections that lead to Burkitt's lymphoma in Africa typically affect the jaw and mouth area, while the (very rare) incidences of Burkitt's lymphoma found in developed countries are more apt to manifest tumors in the abdominal region, most commonly in the intestines, kidneys, or ovaries.

Causes and symptoms

EBV and mononucleosis

EBV is normally transmitted by contact with the saliva of an infected person; it is not ordinarily transmitted through the air. The virus takes about 4–6 weeks to incubate, and thus infected persons can spread the disease to others over a period of several weeks. After entering the patient's mouth and upper throat, the virus infects B cells, which are a certain type of white blood cell produced in the bone marrow. The infected B cells are then carried into the lymphatic system, where they affect the liver and spleen and cause the lymph nodes to swell and enlarge. The infected B cells are also responsible for the fever, swelling of the tonsils, and sore throat that characterize mononucleosis.

Most people who become infected with EBV do not have any symptoms. In children, EBV infection is

WWW.BOOKBAZ.IR

usually asymptomatic; when it does cause symptoms, they are difficult to distinguish from routine mild childhood infections. Teenagers who were not exposed to EBV in childhood have a 35–50% chance of developing infectious mononucleosis (IM) from EBV. The most common symptoms of IM in teenagers are fever, sore throat, and swollen lymph glands. The patient may also have an enlarged spleen and liver.

After the symptoms of mononucleosis go away, the EBV virus remains in a few cells in the patient's throat tissues or blood for the rest of the person's life. The virus occasionally reactivates and may appear in samples of the person's saliva, but it does not cause new symptoms of illness. EBV infection does not cause any problems during **pregnancy**, such as miscarriages or **birth defects**.

EBV and cancer

EBV has been linked to IM in the Western world for decades. It has also become associated consistently with nasopharyngeal cancers in Asia (especially China) and Burkitt's lymphoma in Africa and Papua New Guinea. According to the CDC, EBV is not the sole cause of these two malignancies, but does play an important role in the development of both cancers. The mechanism that allows Epstein-Barr virus to at least help in producing such diverse illnesses in diverse regions of the world has been the subject of increasing research and scrutiny. One theory regarding the higher rate of nasopharyngeal cancer in Asia is that EBV interacts with chemicals called nitrosamines, used in the preparation of salted fish and other preserved foods popular in the region, to trigger changes in cells that lead to cancer.

It is known that EBV is one of the herpesviruses that remain in the human body for life. Under certain, still not-understood conditions, it alters white blood cells normally associated with the immune system, changing the B cells (white blood cells normally associated with making antibodies), and causing them to reproduce uncontrollably. EBV can bind to these white blood cells to produce a solid mass made up of B cells—called Burkitt's lymphoma—or to the mucous membranes of the mouth and nose and cause nasopharyngeal cancer. Since Burkitt's lymphoma typically occurs in people living in moist, tropical climates, the same regions where people usually contract **malaria**, some doctors speculate that the immune system is altered by its response to malaria. When EBV infection occurs, the altered immune system reacts by producing a tumor.

KEY TERMS

B cell—A type of white blood cell produced in the bone marrow that makes antibodies against viruses.

Lymphocyte—Any of a group of white blood cells of crucial importance to the immune system's production of a tailor-made defense against specific invading organisms.

Lymphoma—A group of cancers in which the cells of tissue usually found in the lymph nodes or spleen multiply abnormally.

Malaria—A serious disease prevalent in the tropics. It is caused by parasites and produces severe fever and sometimes complications affecting the kidneys, liver, brain, and blood. It is spread by the Anopheles mosquito and can be fatal.

Nasopharyngeal—Referring to the passage connecting the nasal cavity behind the nose to the top of the throat behind the soft palate.

Though studies about the hereditary tendency of abnormal cell development after EBV infection are incomplete, researchers have found it to be associated with abnormalities on multiple human chromosomes, including chromosomes 1, 2, 3, 4, 5, 6, 8, 9, 11, 13, 14, 15, 16, 17, 22, and the X chromosome.

Diagnosis

The diagnosis of mononucleosis caused by EBV is usually based on the results of blood tests combined with the doctor's examination of the patient's throat and neck. The doctor will also tap on or feel the patient's abdomen to see whether the liver and spleen have become enlarged.

A patient infected by EBV will have an increased number of white blood cells in the blood sample, an increased number of abnormal white blood cells, and antibodies to the Epstein-Barr virus. These antibodies can be detected by a test called the monospot test, which gives results within a day but may not be accurate during the first week of the patient's illness. Another type of blood test for EBV antibodies takes longer to perform but gives more accurate results within the first week of symptoms.

Treatment

Traditional

DRUGS. Because EBV infections are viral in origin, **antibiotics** are ineffective against them. Much

research is geared toward the development of a vaccines effective against both the virus and cancer.

Treatment for mononucleosis caused by EBV consists of self-care at home until the symptoms go away. Patients should rest in bed if possible and drink plenty of fluids. Nonaspirin **pain** relievers like Advil or Tylenol can be taken to bring down the fever and relieve muscle aches and pains. Throat lozenges or gargling with warm salt water may help ease the discomfort of a sore throat.

Because mononucleosis can affect the spleen, patients should avoid vigorous **exercise** or contact sports for at least one month after the onset of symptoms or until the spleen returns to its normal size. This precaution will lower the risk of rupture of the spleen.

With regard to cancers associated with EBV, such **anticancer drugs** as cyclophosphamide or **radiation therapy** have been shown to be effective against Burkitt's lymphoma in four out of five cases.

Alternatives

The goal of alternative treatment is to lower the white blood cell count to normal levels. Treatment often includes such **nutritional supplements** as flaxseed oil or shark cartilage, vitamins—including **vitamins** C and K, and mineral supplements containing magnesium and potassium. Well-conducted randomized clinical trials have not yet been conducted to prove the efficacy of these therapies.

Prognosis

Mononucleosis caused by EBV rarely leads to serious complications. In most patients, the fever goes down in about 10 days but **fatigue** may last for several weeks or months. Some people do not feel normal again for about three months. A patient who feels sick longer than 4 months should go back to the doctor to see whether they have another disease or disorder in addition to mononucleosis. In some cases the patient is diagnosed with **chronic fatigue syndrome** or CFS. The Epstein-Barr virus does not cause CFS; however, it appears to make some patients with mononucleosis more susceptible to developing chronic fatigue syndrome.

The prognosis for nasopharyngeal cancer associated with EBV in adults is poor, because about 60% of these cancers have already metastasized to other regions of the head and neck by the time diagnosis is made. The prognosis for this type of cancer in children is also relatively poor. The survival rates for children treated only with radiation therapy are about 45%. When **chemotherapy** and radiation therapy are used together, long-term survival rates range from 55–80%.

Prevention

There is no vaccine that can prevent mononucleosis caused by EBV. In addition, the fact that many people can be infected with the virus and transmit it to others without having symptoms of the disease means that mononucleosis is almost impossible to prevent. The best precautionary measure is for patients who have been diagnosed with mono to avoid kissing or other close personal contact with others, and to wash their drinking glasses, food dishes, and eating utensils separately from those of other family members or friends for several days after the fever goes down. It is not necessary for people with mono to be completely isolated from other people, however.

Because the Epstein-Barr virus remains in the body after the symptoms of mononucleosis go away, people who have had IM should not donate blood for at least 6 months after their symptoms started.

Epstein-Barr virus test

Definition

The **Epstein-Barr virus** (EBV) test is a blood test, or group of tests, to determine the presence or absence of antibodies in the blood stream directed against proteins of EBV, the cause of **infectious mononucleosis**.

Purpose

The test is primarily used to detect the presence of EBV. The pattern of the antibodies detected can also tell if a person has never been infected with EBV, if it is their first infection with EBV (called the primary infection), or if the infection occurred in the more distant past. These tests are mostly utilized in the diagnosis of EBV-associated infectious mononucleosis when the more common diagnostic test, the heterophile antibody, is negative, or in situations where the infection is manifesting unusual symptoms. Therefore, the tests are often not needed in a situation where a doctor believes that a person has mononucleosis and the heterophile test (also called the monospot test) is positive.

Description

An EBV test is more often performed in a consulting laboratory than at a physician's office or in a hospital laboratory. Like most antibody tests, it is performed on serum, the liquid part of the blood obtained after the whole blood is allowed to clot in a tube. Antibodies can be detected against several components of EBV. These components are the EBV early antigen (EA), the viral capsid antigen (VCA), and the nuclear antigen (EBNA). These several antigens are different proteins that are produced in the process (stages) of the virus' growth.

At the time of infection with EBV, antibodies to EA are found and usually last for four to six months. This antibody, however, persists substantially longer in about 10% of people who have had EBV infection in the more remote past. The absence of antibody to EA when other EBV antibodies are present strongly suggests that first time infection with EBV occurred in the past.

Antibody to VCA is found both early and late in EBV infection. At the time of infection, antibody of both the IgM and IgG types are detectable. After four to six months, usually only the IgG antibody against VCA can be found.

Unlike antibodies to EA and VCA, antibody to EBNA does not usually develop until recovery from first time infection of the virus. Therefore, finding detectable amounts of antibody to EBNA during an illness that might be caused by EBV makes the causal relationship very unlikely.

Precautions

As in any blood test, standard precautions should be performed to prevent infection at the site where the blood is obtained, and to prevent excess bleeding. Normally, the site is cleaned with an antiseptic liquid prior to the blood being obtained. A sterile, nonreusable needle and syringe are used, and once the needle is removed, pressure is placed at the site until bleeding has stopped.

Preparation

The skin area from which the blood sample will be obtained is wiped with an antiseptic such as alcohol or iodine.

Aftercare

The aftercare is similar to that for any blood test. Usually, pressure is applied to the area for several moments until bleeding stops. If the results are difficult to interpret, it may be necessary to retest later, after one to three weeks. The change in the amounts of antibody detected between the two tests can be particularly useful in helping to make a diagnosis.

Risks

There are no risks over and above those of having blood drawn for any other purpose. These tests are more expensive than many other blood tests but are usually covered by medical insurance.

Results

The pattern of the three antibodies can be used to determine whether the person has never been infected with EBV (is susceptible to infection), is currently or was recently infected with EBV for the first time, or has had first time infection with EBV sometime in the past (more than six months ago). Most adults over the age of 20 have been infected with EBV at some point in their lives.

The results for susceptibility are:

- antibody to EA = negative
- antibody to VCA (either IgM or IgG) = negative
- antibody to EBNA = negative

The results for past infection are:

- antibody to EA = negative (90% of time)
- antibody to VCA IgM = negative
- antibody to VCA IgG = positive
- antibody to EBNA = positive

It is important to realize that EBV, like all the human herpes viruses, does not totally leave the body after the patient recovers from illness. With EBV, the virus will intermittently recur in the saliva of people without any symptoms. Such people will have a test pattern of previous infection. It is this group of people who can transmit EBV to others without themselves being ill.

Abnormal results

The results for current or recent infection are:

- antibody to EA = positive
- antibody to VCA IgM = positive
- antibody to VCA IgG = positive
- antibody to EBNA = negative

Without the pattern of the three antibodies, it can be difficult to accurately interpret the results. The presence of antibody to VCA IgM is the best single test for current or recent first-time infection.

Erectile dysfunction

Definition

Erectile dysfunction (ED) is the consistent inability to achieve or maintain a penile erection that is sufficient for satisfactory sexual intercourse.

Demographics

It is estimated that 15–30 million American men suffer from some degree of ED. Of these, 10–20 million have severe ED resulting in the complete inability to attain or maintain a penile erection. As the population ages, the number of American men with ED is projected to increase by nearly 10 million by 2025. The worldwide incidence of ED is projected to be more than 320 million by 2025.

The incidence of ED increases with advancing age, along with the incidence of chronic disorders and conditions that are commonly associated with ED, including diabetes, **hypertension**, and cardiovascular disease. It is estimated that 26% of men in their

WWW.BOOKBAZ.IR

50s, 40% of men in their 60s, and 77% of men 75 and older have some degree of ED. ED is notorious for being underreported, undiagnosed, and under–treated due to its perceived stigma. It is estimated that 70% of ED cases remain undiagnosed. In a survey of general medical practice, less than 12% of men with ED reported having received treatment. Thus, the true incidence of ED may be much higher than most estimates.

Description

ED is defined as the consistent inability to achieve or maintain an erection, usually associated with **fatigue**, anger, depression, or other stressful emotions. The term "impotence" is now rarely used because of its association with weakness and lack of power.

Penile erection occurs when the penis becomes engorged with blood. The anatomical compartments—the two corpora cavernosa and the corpus spongiosum—can be distended with up to seven times the normal amount of blood. This change results in an erection in association with the relaxation of the penile muscles.

The sequence of events resulting in penile erection is complex. Erection is usually initiated by sexual arousal stimuli in the brain as a result of visual, auditory, or olfactory sensations or erotic thoughts. Tactile (touch) sensations of the penis, acting through the spinal cord, play a similar role. Sexual arousal results in the release of nitric oxide from specialized cells. Nitric oxide causes the formation of cyclic glutamine monophosphate (cGMP), which is responsible for dilating the blood vessels of the penis and relaxing the penile muscles, enabling increased blood flow and erection. Compression of the dilated blood vessels against the firm outer lining of the penis prevents the blood from escaping and perpetuates the erection. An enzyme called phosphodiesterase 5 (PDE5) causes the breakdown of cGMP and, along with nerves from the sympathetic nervous system, enables the penis to return to its flaccid relaxed state. Any defect in this complex cascade of events can result in ED.

Sex is an important quality–of–life issue for adults of all ages and ED usually results in a reduced quality of life. Many affected men experience depression, distress, and relationship difficulties as a result of ED. Despite this, men with ED often fail to seek help. Reasons for this failure include:

- ignorance of the availability of safe and effective ED therapies
- inadequate information from physicians about the timing of medications, the need for preliminary sexual arousal, and other factors
- concerns about marital discord and a lack of partner support
- concerns about invasiveness, adverse effects, discomfort, inconvenience, and cost of therapies
- high rates of discontinuation of therapy due to inadequate responses and adverse effects

Risk factors

ED is frequently associated with vascular conditions such as hypertension and coronary artery **heart disease** and may even serve as marker for detection of cardiovascular disorders. Additionally, ED is associated with depression that is distinct from depression resulting from ED. Lifestyle factors—such as **obesity**, physical inactivity, cigarette **smoking**, and excessive intake of alcohol—are also risk factors for ED.

Causes and symptoms

Because of the complicated nature of the human sexual response and the complex **physiology** of penile erection and relaxation, it is often difficult or even impossible to determine the cause of an individual case of ED precisely. Often ED is the result of multiple factors. Normal erectile function requires the coordination of vascular, neurologic, hormonal, and psychological components and any condition that interferes with one or more of these processes can result in ED.

Although the incidence of ED increases with advancing age it is no longer regarded as an inevitable consequence of **aging**. Likewise, whereas most cases of ED were once considered primarily psychological and/or psychiatric in origin, it is now recognized that organic, non–psychological factors play a much more significant role, with physical causes being responsible for at least 80% of cases. Significant psychological and social factors—such as guilt, depression, **anxiety**, tension, or marital discord—are often present in addition to one or more underlying physical components:

- Diabetes mellitus is the single most common cause of ED, as a result of combined nerve and blood vessel damage. As many as 50% of male diabetics have ED.
- Hardening of the arteries (arteriosclerosis) is the most common vascular (circulation–related) cause of ED. Diseases of the aorta or the arteries supplying the pelvis and penis or damage to arteries from trauma, surgery, or irradiation can cause ED. Surgery involving the prostate gland may affect both arteries and nerves.

- A variety of diseases and factors can influence penile circulation. For example Peyronie's disease, characterized by fibrous tissue and bending of the penis, limits the expandability of penile tissues and prevents venous compression, enabling blood to exit the penis. Arteriosclerotic plaque, injury to the inner lining blood vessels from trauma, surgery, or irradiation, or aortic occlusion (blockage in a main artery leading out of the heart) can compromise penile blood flow and prevent erection.
- Neurological causes of ED include diseases of the brain and spinal cord, such as Alzheimer's disease or multiple sclerosis, respectively.
- Hormonal or endocrine causes of ED are uncommon, although deficient testicular function and low circulating levels of the male sex hormone testosterone can result in erectile dysfunction. These are referred to as hypogonadism and can be due to congenital abnormalities or testicular disease.
- Various classes of medications can cause ED, although not all drugs within a class have the same effects. For example some antidepressants are associated with ED, whereas the antidepressant trazodone (Desyrel) tends to prolong penile erection. Some high blood pressure medications, central nervous system medications such as methyldopa for Parkinson's disease, sedatives or tranquilizers such as barbiturates, and anti–anxiety medications such as diazepam (Valium) also can cause ED.
- Tobacco, alcohol, and illicit drugs, including heroin, can cause ED.
- Psychological factors—including stress, fatigue, depression, guilt, low self–esteem, or negative feelings for or by a sexual partner—can precipitate ED. Depressive symptoms or difficulty coping with anger can be particularly detrimental.
- ED is the main symptom of a mental disorder known as male erectile disorder.

Although the primary ED symptom is the inability to attain or maintain an adequate erection for completed sexual activity, patterns of ED vary. Some men are unable to attain any erection. Others cannot maintain an erection adequate for penetration. Some men lose their erection during sexual intercourse. Others experience an erection only upon awakening or during masturbation.

Diagnosis

Examination

Thorough medical, psychosocial (both psychological and social), and sexual histories are an essential first step in the diagnosis of ED. A general medical history can indicate the existence of ED–associated conditions such as high blood pressure, diabetes, or arteriosclerosis, as well as medications that may contribute to ED and any history of substance abuse. A psychosocial history includes current sexual practices, the existence of stresses or performance anxiety, and any special circumstances under which ED occurs. The sexual partner's participation in the taking of a psychosocial history can be beneficial. The sexual history assists in distinguishing ED from other abnormalities in sexual function, such as ejaculatory and orgasmic disturbances or loss of sexual desire. The patient's sexual history includes:

- the frequency and duration of sexual intercourse
- the degree and quality of penile erections
- nocturnal erections
- the success or failure of penetration
- any sexual dysfunction of the partner, such as painful intercourse (dyspareunia) or vaginal dryness

Self–administered questionnaires can assist in the evaluation of sexual function. The International Index of Erectile Function (IIEF) is the most widely used. It addresses:

- sexual desire
- erectile function
- orgasmic function
- intercourse satisfaction
- overall satisfaction

KEY TERMS

Dopamine—A chemical in brain tissue that transmits nerve impulses (a neurotransmitter) and helps to regulate movement and emotions.

Hypertension—Abnormally high arterial blood pressure, which if left untreated can lead to heart disease and stroke.

Hypogonadism—Functional incompetence of the male gonads, with impaired production of hormones and germ cells.

Prolactin—A hormone produced by the pituitary gland.

Prostate—The walnut–shaped gland that surrounds the urethra at the neck of the bladder in males and supplies fluid for semen.

Testosterone—The primary male sex hormone.

Urethra—The tube in the penis that discharges urine from the bladder to the outside of the body.

WWW.BOOKBAZ.IR

A routine **physical examination** is conducted with special emphasis on the genitourinary, circulatory, and neurologic systems. The physician may look for evidence of **hypogonadism** or congenital conditions causing defective testicular function. The genitalia are examined for testicular size and consistency and penile deformities. A **rectal examination** can evaluate the size and consistency of the prostate gland and certain muscular reflexes. Vital signs such as blood pressure and pulse are measured.

Tests

Blood tests and/or other assessments for high blood **cholesterol**, hypertension, coronary artery heart disease, and depression may be performed, since ED can be a marker or symptom of such disorders. Blood levels of the hormones testosterone and prolactin may be measured.

Procedures

There are several diagnostic procedures for ED:

- Duplex Doppler ultrasonography provides information about both arterial and venous blood flow.
- Pharmacological testing involves the injection of a small amount of an agent—such as 10 micrograms of alprostadil (prostaglandin E1)—that produces an erection in a patient with normal erectile function.
- Nocturnal studies are used to identify erectile dysfunction due to organic causes. Patients are monitored in a sleep laboratory for nocturnal erections during sleep, since men with physiologically normal erectile function have erections during sleep. A self–test can also be performed.

Treatment

Traditional

There are a variety of treatment options for ED, including a combination of therapies:

- Psychosexual therapy, individual psychotherapy, or couples therapy may be recommended.
- Vacuum constriction device therapy involves a mechanical device for increasing penile blood flow and erection.
- Various types of penile prostheses can be surgically inserted into the penis to produce erections.
- In rare cases surgery may be used to correct a defect that interferes with penile erection.

Drugs

There are various drug treatments for ED:

- Adjustment of prescription or over–the–counter medications may be required.
- PDE5 inhibitors relax the muscles in the penis to increase penile blood flow and produce an erection. This class of drugs includes sildenafil (Viagra), vardenafil (Levitra), and tadalafil (Cialis). These should not be used by men who take nitroglycerin for heart problems because they can cause a sudden drop in blood pressure. PDE5 inhibitors also have been associated with an increased risk for a rare condition called nonarteritic ischemic optic neuropathy, which can lead to sudden vision loss.
- Apomorphine is a morphine derivative that targets dopamine receptors to facilitate erections.
- Alpha–adrenergic blockers target adrenergic receptors in smooth muscles, causing the blood vessels to dilate more easily.
- Intracavernous injection therapy (ICIT) is the injection of penile structures with the drugs alprostadil (Caverject), papaverine (Pavabid), or phentolamine, which promote blood flow.
- Intraurethral therapy is the insertion of alprostadil into the urethra to increase blood flow and muscle relaxation.

Alternatives

Herbal remedies for ED include:

- dehydroepiandrosterone (DHEA)
- ginkgo
- ginseng
- L–arginine
- yohimbe
- epimedium (horny goat weed)
- zinc
- folic acid and vitamin E in combination with Viagra

Alternative treatments should be used with care, as the benefits of many such treatments have not been confirmed by scientific research.

Home remedies

A first step in ED treatment is the alteration or elimination of modifiable risk factors or causes, including smoking, obesity, and substance or alcohol abuse.

Prognosis

A better understanding of ED, combined with new, more effective therapies, has markedly improved the prognosis. It is estimated that at least 65% of all ED cases can be treated successfully. The modification of risk factors—such as physical inactivity, smoking, excessive alcohol intake, certain medications, and obesity—improve the prognosis. Other risk factors—including aging and conditions such as diabetes or pelvic surgery affecting nerves—negatively impact the prognosis.

Prevention

Physicians can help prevent ED by prescribing high blood pressure and other medications that are not associated with ED for their at–risk patients. Various lifestyle changes can help prevent ED. These include:

- not smoking
- losing weight
- not abusing alcohol or other substances

Erectile dysfunction treatment

Definition

Erectile dysfunction (ED)—the consistent inability to achieve or maintain an erection long enough to engage in satisfactory sexual intercourse—is most often treated with drugs. However, in some cases, more invasive techniques or devises must be used to treat ED.

Purpose

The purpose of ED treatment is to enable men to achieve and maintain erections of sufficient strength and duration to engage in sexual intercourse. This usually requires maintaining an erection for 30–60 minutes.

Demographics

It is estimated that 15–30 million American men suffer from some degree of ED and 10–20 million of these men are completely unable to attain or maintain a penile erection. About 75% of men in the general population who have tried ED drugs have found them to be helpful. Although these drugs have revolutionized ED

WWW.BOOKBAZ.IR

treatment, some men—for example **prostate cancer** patients and those with ED stemming from psychological issues—often require alternative treatments.

Description

Sexual arousal normally causes the release of nitric oxide from specialized cells. Nitric oxide causes the formation of cyclic glutamine monophosphate (cGMP), which is responsible for dilating the blood vessels of the penis and relaxing the penile muscles, enabling increased blood flow and erection. Compression of the dilated blood vessels against the firm outer lining of the penis prevents blood from escaping and perpetuates the erection. An enzyme called phosphodiesterase–5 (PDE5) breaks down cGMP, resulting in decreased blood flow to the penis, which then returns to its flaccid relaxed state. The most common drugs for treating ED are PDE5 inhibitors.

A first step in ED treatment is the alteration or elimination of modifiable factors that can cause the disorder. These include **smoking**, **obesity**, and alcohol or other substance abuse. An adjustment in prescription or over–the–counter medications that can cause ED also may be required. ED that is caused, at least in part, by psychosocial factors may be treated with psychosexual therapy, individual **psychotherapy**, or couples therapy.

There are three prescription oral PDE5 inhibitors available in the United States for treating physical causes of ED: **sildenafil citrate** (Viagra), vardenafil hydrochloride (Levitra), and tadalafil (Cialis). These drugs increase the supply of nitric oxide to open blood vessels and relax muscles in the penis, thereby increasing penile blood flow and producing an erection. Once sexual activity is completed, blood flow to the penis decreases and the erection is lost.

Available dosages of PDE5 inhibitors are as follows:

- Viagra: 25, 50, and 100 mg, with an average recommended dose of 50 mg
- Levitra: 2.5, 5, 10, and 20 mg tablets
- Cialis: 5, 10, and 20 mg tablets, with 10 mg as the recommended starting dose. Some evidence indicates that higher doses of sildenafil and vardenafil, but not tadalafil, provoke better responses than lower doses. ED drugs are covered by most insurance plans.

The three PDE5 inhibitors are very similar and appear to be equally effective. Viagra and Levitra must be taken without food and are effective for up to four hours. Cialis can be taken with or without food and is effective for up to 36 hours.

Other drugs that are sometimes used to treat ED include:

- testosterone, for hypogonadism in which levels of the male sex hormone are low
- apomorphine, a morphine derivative that targets dopamine receptors to facilitate erections
- alpha–adrenergic blockers, which target adrenergic receptors in smooth muscles causing blood vessels to dilate more readily

Herbal remedies that may improve ED in some cases include:

- dehydroepiandrosterone (DHEA)
- ginkgo
- ginseng
- L–arginine
- yohimbe
- epimedium (horny goat weed)
- zinc
- folic acid and vitamin E in combination with Viagra

Alternative treatments should be used with care, as the benefits of many such treatments have not been confirmed by scientific research.

Intracavernous injection therapy (ICIT) is the injection of penile structures with drugs that promote blood flow. The drugs are injected into the corpora cavernosa—the erectile tissues that form the bulk of the penis and that become engorged with blood during an erection. Alprostadil (prostaglandin E1; Caverject) and papaverine hydrochloride (Pavabid) relax the smooth muscle tissue to enhance blood flow into the penis. Injection therapy often involves a three–drug combination commonly referred to as the "Knoxville formula," apparently after the city of its original introduction. Although there are a number of slightly different formulations in use, they all involve alprostadil, papaverine, and phentolamine mesylate.

Intraurethral therapy or MUSE (medical urethral system for erection) involves administering alprostadil into the urethral opening of the penis. A thin tube—about the width of a spaghetti noodle—is inserted into the urethral opening and a plunger is pressed to deliver a tiny pellet containing alprostadil. The drug must be injected shortly before intercourse. It takes about 10 minutes to achieve an erection that lasts about one hour.

Vacuum pump therapy involves inserting the penis into a clear plastic cylinder and pumping air out of the cylinder to form a partial vacuum, which helps draw blood into the corpora cavernosa. A special ring is placed over the base of the penis to trap the blood.

Implanted **penile prostheses** are usually a last resort for treating ED. These are implanted in the corpora cavernosa to make the penis rigid without the need for blood flow. The semi–rigid type of prosthesis consists of a pair of flexible silicone rods that can be bent up or down. An inflatable device consists of cylinders implanted in the corpora cavernosa, a fluid reservoir implanted in the abdomen, and a pump placed in the scrotum. Squeezing the pump moves fluid into the cylinders to inflate them and make them rigid. Squeezing the pump again reverses the process. Men can resume sexual activity six ro eight weeks after implantation surgery.

In rare cases when narrowed or diseased veins are responsible for ED, surgery may be required to reroute the blood flow into the corpora cavernosa or to remove leaking blood vessels that interfere with penile erection.

Origins

Drugs for treating ED are relatively new:

- Alprostadil was first approved for ED by the U.S. Food and Drug Administration (FDA) in 1995.
- Sildenafil was originally developed in 1991 as a treatment for angina (chest pain). Viagra received FDA approval as a treatment for ED in 1998.
- Levitra and Cialis received FDA approval in 2003.

Benefits

It is estimated that at least 65% of all ED cases can be treated successfully. Addressing risk factors, such as physical inactivity, smoking, excessive alcohol intake, certain medications, and obesity, improves the prognosis. Levitra can often improve erectile function even in men with other medical problems, such as diabetes or prostate surgery. Cialis has also been shown to improve erectile function in most men, including those with severe ED. Cialis does not need to be taken on an empty stomach and is not affected by high–fat foods.

Precautions

- PDE5 inhibitors alone do not result in an erection; nor do they increase sexual desire. They require sexual stimulation and arousal to be effective.
- PDE5 inhibitors cannot be taken more than once a day.
- Viagra and Levitra should be taken on an empty stomach to be effective.
- High–fat foods can interfere with the absorption of Viagra.
- Men who experience cardiovascular symptoms—such as dizziness, chest or arm pain, or nausea—after taking a PDE5 inhibitor should cease all sexual activity and consult their physician before taking the drug again.
- PDE5 inhibitors should not be used by women or children or by men without ED.
- Many ED treatments, often labeled as "dietary supplements," are available online. The FDA has warned consumers that these products may contain unlabeled PDE5 inhibitors that should not be used except under a physician's supervision, as well as various other substances that may be harmful.
- Implantable penile prostheses cause the penis to always be erect.
- Although inflatable implants allow for planned erections, they have a slightly higher malfunction rate than silicone rods.
- Implants permanently destroy the ability to achieve a natural erection.

PDE5 inhibitors do not cause side effects in most people; however higher doses increase the risk of side effects. The most common side effects of PDE5 inhibitors are mild to moderate **headache** or nausea, which usually disappear within a few hours. Less common side effects include:

- flushing
- indigestion
- stuffy or runny nose
- back pain and muscle aches with Levitra and Cialis
- temporary vision changes, including "blue vision," with Viagra

Geriatric

ED treatments may be less effective in geriatric patients. Men over age 65 should start with the lowest possible dose of a PDE5 inhibitor.

Other conditions and allergies

- Since sexual activity can put stress on the heart, men with heart conditions should talk to their physicians about the advisability of sexual activity prior to using any ED treatment.
- ED treatments may be less effective in men who have had pelvic surgery affecting nerves.
- PDE5 inhibitors are only about 60–65% effective in diabetics.
- Men with kidney or liver impairment should begin with the lowest possible dose of a PDE5 inhibitor.

WWW.BOOKBAZ.IR

- PDE5 inhibitors should not be used by men who take nitroglycerin or other nitrate drugs for heart problems.
- Men who use alpha–blockers—sometimes prescribed for high blood pressure or prostate problems—also should not take PDE5 inhibitors, since such combinations can cause an unsafe drop in blood pressure.
- Numerous other drugs can interact with PDE5 inhibitors.

PDE5 inhibitors are known to increase cardiovascular nerve activity and can trigger temporary **hypotension** (low blood pressure). They may not be safe for patients with:

- atherosclerosis
- heart problems including angina (chest pains), abnormal heart rhythms (arrhythmias), heart failure, or recent heart attack
- uncontrolled high or low blood pressure
- stroke within the past six months
- eye problems, such as retinitis pigmentosa, or relatives with certain eye problems
- sickle cell anemia, leukemia, or other health problems that can cause priapism

Preparation

Viagra is taken 60 minutes or more prior to sexual activity. Levitra and Cialis are taken 30 minutes or more before sex.

Aftercare

Blood pressure should be monitored after taking PDE5 inhibitors.

Risks

Priapism, a prolonged erection, is a very rare side effect of all prescription ED medications. Alprostadil and papaverine sometimes cause painful erections or priapism that must be treated with a shot of epinephrine. Any erection lasting more than four hours requires immediate medical attention because priapism can permanently damage the penis.

There are other risks associated with ED treatments:

- PDE5 inhibitors increase the risk of heart attack in patients with unstable heart disease or who take nitrate medications.
- PDE5 inhibitors may be associated with an increased risk for a rare condition called nonarteritic ischemic optic neuropathy, which can lead to sudden vision loss.

KEY TERMS

Angina—A condition in which lack of blood to the heart causes severe chest pain.

Arrhythmia—An irregularity in the normal rhythm or force of the heartbeat.

Atherosclerosis—Hardening of the arteries; an arterial disease in which raised areas of degeneration and cholesterol deposits (plaques) form on the inner surfaces of the arteries.

Dopamine—A chemical in brain tissue that transmits nerve impulses (a neurotransmitter) and helps to regulate movement and emotions.

Corpora cavernosa—The pair of columns of erectile tissue on either side of the penis that, together with the corpus spongiosum, produce an erection when filled with blood.

Phosphodiesterase–5 (PDE5) inhibitors—The drugs Viagra, Levitra, and Cialis, which are used to treat ED.

Priapism—A prolonged erection lasting more than four hours.

Testosterone—The primary male sex hormone.

Urethra—The tube in the penis that discharges urine from the bladder to the outside of the body.

- The injection of ED medications is often painful. Alprostadil injection can cause pain and burning in the urethra for about five to 15 minutes.
- Vacuum pump therapy can cause bruising if the vacuum is left on for too long.

Ergotamine *see* **Antimigraine drugs**

Erosive gastritis *see* **Gastritis**

Erysipelas

Definition

Erysipelas is a skin infection that often follows **strep throat**.

Description

Erysipelas, also called St. Anthony's fire, is caused by infection by Group A *Streptococci*. This same type of bacteria is responsible for such infections as strep throat, and infections of both surgical and other kinds of **wounds** in the skin. The infection occurs most often in young infants and the elderly.

Causes and symptoms

Erysipelas usually occurs rather abruptly. When the preceding infection was strep throat, the rash begins on the face. Occasionally, when the preceding infection was of a wound from an injury or operation, the rash will appear on an arm or leg.

Classically, the usual presentation is a bright-red, butterfly-shaped rash appearing across the bridge of the nose and the cheeks. It is hot to the touch, painful, shiny, and swollen, with clearly defined margins. The edges of the rash are a raised ridge, hard to the touch. There may be fluid-filled bumps scattered along the area. The rash spreads rapidly. Some patients have swelling of the eyelids, sometimes so severe that their eyes swell shut. The patient may have **fever**, chills, loss of energy, **nausea and vomiting**, and swollen, tender lymph nodes. In severe cases, walled-off areas of pus (abscesses) may develop beneath the skin. If left untreated, the streptococcal bacteria may begin circulating in the bloodstream (a condition called **bacteremia**). A patient may then develop an overwhelming, systemic infection called **sepsis**, with a high risk of death.

Diagnosis

The rash of erysipelas is very characteristic, raising the practitioner's suspicion towards that diagnosis, especially when coupled with a history of recent strep infection. Attempts to culture (grow) the bacteria from a sample of the rash usually fail. When the bacteria are present in the blood, they may be grown in a laboratory, and identified under a microscope. Other laboratory tests involve reacting fluorescently-tagged antibodies with a sample of the patient's infected tissue. This type of test may be successful in positively identifying the streptococcal bacteria.

WWW.BOOKBAZ.IR

KEY TERMS

Bacteremia—The presence of bacteria in the blood.

Streptococcus—A bacteria that causes erysipelas and strep throat, as well as other infections.

Treatment

Penicillin is the drug of choice for treating erysipelas. It can usually be given by mouth, although in severe cases (or in cases of diagnosed bacteremia) it may be given through a needle placed in a vein (intravenously).

Even with antibiotic treatment, swelling may continue to spread. Other symptoms, such as fever, **pain**, and redness, usually decrease rapidly after penicillin is started. Cold packs and pain relievers may help decrease discomfort. Within about five to 10 days, the affected skin may begin drying up and flaking off.

Prognosis

With prompt treatment, the prognosis from erysipelas is excellent. Delay of treatment, however, increases the chance for bacteremia and the potential for death from overwhelming sepsis. This is particularly true of people with weakened immune systems (babies, the elderly, and people ill with other diseases, especially **AIDS**). Frequently, an individual who has had erysipelas will have it occur again in the same location.

Prevention

Prevention involves appropriate and complete treatment of **streptococcal infections**, including strep throat and wound infections.

Resources

PERIODICALS

De Godoy, Jose Maria Pereira, et al. "Epidemiological data and comorbidities of 428 patients hospitalized with erysipelas." *Angiology* (July 2010): 492–494.

Rosalyn Carson-DeWitt, MD

Erythema infectiosum *see* **Fifth disease**

KEY TERMS

Herpes virus—Viruses that can infect the skin, mucous membranes, and brain, and they are responsible for such diseases as herpes simplex, chicken pox, and shingles.

Mycoplasma pneumonia—An incomplete bacterium that infects the lung.

Erythema multiforme

Definition

Erythema multiforme is a skin disease that causes lesions and redness around the lesions.

Description

Erythema multiforme appears on the skin and the mucous membranes (the lining of the mouth, digestive tract, vagina, and other organs). Large, symmetrical red blotches appear all over the skin in a circular pattern. On mucous membranes, it begins as blisters and progresses to **ulcers**. A more advanced form, called Stevens-Johnson syndrome, can be severe and even fatal.

Causes and symptoms

Erythema multiforme has many causes, most commonly are drugs. Penicillin, **sulfonamides**, certain **epilepsy** drugs, **aspirin**, and **acetaminophen** are the most likely medication-induced causes. Erythema multiforme can also be caused by certain diseases. Herpes virus and mycoplasma **pneumonia** are likely infectious causes.

Diagnosis

The appearance of the rash is sufficiently unique to identify it on sight. Having identified it, the physician will determine the underlying cause.

Treatment

Erythema multiforme is inadvertently treated when the causative agent, whether it be a drug or a disease, is treated. In severe cases, cortisone-like medication is often used along with general supportive measures and prevention of infection.

Prognosis

As a rule, the rash abates by itself without damaging the skin. Only in the case of infection, severe

blistering, or continued use of an offending drug do complications occur.

Erythema nodosum

Definition

Erythema nodosum is a skin disorder characterized by painful red nodules appearing mostly on the shins.

Description

Erythema nodosum is an eruption of tender red lumps on both shins and occasionally the arms and face. Bruising often accompanies the nodule formation. Erythema nodosum is most prevalent in young adults.

Causes and symptoms

Erythema nodosum can be caused by many important and treatable diseases. Among them are **tuberculosis**, several fungal lung infections, **leprosy**, inflammatory bowel disease, and some potentially dangerous bacterial infections. Drugs can also induce erythema nodosum. The most common are penicillin, **sulfonamides**, and birth control pills.

Diagnosis

There are a few other skin eruptions that mimic erythema nodosum, so the physician may have to perform a biopsy to sort them out. There are a few types of panniculitis, fat inflammation, that may signal a cancer somewhere in the body, and there are other kinds of inflammation that may confuse the diagnosis.

Once the skin problem has been diagnosed, its underlying cause must then be identified. A lengthy evaluation may ensue, and often times the cause remains unknown.

KEY TERMS

Biopsy—Surgical removal of tissue for diagnostic purposes.

Panniculitis—Inflammation of fatty tissue.

Treatment

Painful nodules can be treated with mild **pain** killers and local application of ice packs. Medical attention will be directed toward the underlying disease.

The nodules will eventually disappear, leaving no trace behind.

Erythremia *see* **Polycythemia vera**

Erythroblastosis fetalis

Definition

Erythroblastosis fetalis refers to two potentially disabling or fatal blood disorders in infants: Rh incompatibility disease and ABO incompatibility disease. Either disease may be apparent before birth and can cause fetal death in some cases. The disorder is caused by incompatibility between a mother's blood and her unborn baby's blood. Because of the incompatibility, the mother's immune system may launch an immune response against the baby's red blood cells. As a result, the baby's blood cells are destroyed, and the baby may suffer severe anemia (deficiency in red blood cells), brain damage, or death.

Description

Red blood cells carry several types of proteins, called antigens, on their surfaces. The A, B, and O antigens are used to classify a person's blood as type A, B, AB, or O. Each parent passes one A, B, or O antigen gene to their child. How the genes are paired determines the person's blood type.

WWW.BOOKBAZ.IR

A person who inherits an A antigen gene from each parent has type A blood; receiving two B antigen genes corresponds with type B blood; and inheriting A and B antigen genes means a person has type AB blood. If the O antigen gene is inherited from both parents, the child has type O blood; however, the pairing of A and O antigen genes corresponds with type A blood; and if the B antigen gene is matched with the O antigen gene, the person has type B blood.

Another red blood cell antigen, called the Rh factor, also plays a role in describing a person's blood type. A person with at least one copy of the gene for the Rh factor has Rh-positive blood; if no copies are inherited, the person's blood type is Rh-negative. In **blood typing**, the presence of A, B, and O antigens, plus the presence or absence of the Rh-factor, determine a person's specific blood type, such as A-positive, B-negative, and so on.

A person's blood type has no effect on health. However, an individual's immune system considers only that person's specific blood type, or a close match, acceptable. If a radically different blood type is introduced into the bloodstream, the immune system produces antibodies, proteins that specifically attack and destroy any cell carrying the foreign antigen.

Determining a person's blood type is very important if she becomes pregnant. Blood cells from the unborn baby (fetal red blood cells) can cross over into the mother's bloodstream, especially at delivery. If the mother and her baby have compatible blood types, the crossover does not present any danger. However, if the blood types are incompatible, the mother's immune system manufactures antibodies against the baby's blood.

Usually, this incompatibility is not a factor in a first **pregnancy**, because few fetal blood cells reach the mother's bloodstream until delivery. The antibodies that form after delivery cannot affect the first child. In later pregnancies, fetuses and babies may be in grave danger. The danger arises from the possibility that the mother's antibodies will attack the fetal red blood cells. If this happens, the fetus or baby can suffer severe health effects and may die.

There are two types of incompatibility diseases: Rh incompatibility disease and ABO incompatibility disease. Both diseases have similar symptoms, but Rh disease is much more severe, because anti-Rh antibodies cross over the placenta more readily than anti-A or anti-B antibodies. (The immune system does not form antibodies against the O antigen.) Therefore, a greater percentage of the baby's blood cells are destroyed by Rh disease.

Both incompatibility diseases are uncommon in the United States due to medical advances over the last 50 years. For example, prior to 1946 (when newborn blood transfusions were introduced) 20,000 babies were affected by Rh disease yearly. Further advances, such as suppressing the mother's antibody response, have reduced the incidence of Rh disease to approximately 4,000 cases per year.

Rh disease only occurs if a mother is Rh-negative and her baby is Rh-positive. For this situation to occur, the baby must inherit the Rh factor gene from the father. Most people are Rh-positive. Only 15% of the Caucasian population is Rh-negative, compared to 5–7% of the African-American population and virtually none of Asian populations.

ABO incompatibility disease is almost always limited to babies with A or B antigens whose mothers have type O blood. Approximately one-third of these babies show evidence of the mother's antibodies in their bloodstream, but only a small percentage develop symptoms of ABO incompatibility disease.

Cause and symptoms

Rh disease and ABO incompatibility disease are caused when a mother's immune system produces antibodies against the red blood cells of her unborn child. The antibodies cause the baby's red blood cells to be destroyed and the baby develops anemia. The baby's body tries to compensate for the anemia by releasing immature red blood cells, called erythroblasts, from the bone marrow.

The overproduction of erythroblasts can cause the liver and spleen to become enlarged, potentially causing liver damage or a ruptured spleen. The emphasis on erythroblast production is at the cost of producing other types of blood cells, such as platelets and other factors important for blood clotting. Since the blood lacks clotting factors, excessive bleeding can be a complication.

The destroyed red blood cells release the blood's red pigment (hemoglobin) which degrades into a yellow substance called bilirubin. Bilirubin is normally produced as red blood cells die, but the body is only equipped to handle a certain low level of bilirubin in the bloodstream at one time. Erythroblastosis fetalis overwhelms the removal system, and high levels of bilirubin accumulate, causing hyperbilirubinemia, a condition in which the baby becomes jaundiced. The **jaundice** is apparent from the yellowish tone of the baby's eyes and skin. If hyperbilirubinemia cannot be controlled, the baby develops kernicterus. The term kernicterus means that bilirubin is being deposited in the brain, possibly causing permanent damage.

Other symptoms that may be present include high levels of insulin and low blood sugar, as well as a condition called hydrops fetalis. Hydrops fetalis is characterized by an accumulation of fluids within the baby's body, giving it a swollen appearance. This fluid accumulation inhibits normal breathing, because the lungs cannot expand fully and may contain fluid. If this condition continues for an extended period, it can interfere with lung growth. Hydrops fetalis and anemia can also contribute to heart problems.

Diagnosis

Erythroblastosis fetalis can be predicted before birth by determining the mother's blood type. If she is Rh-negative, the father's blood is tested to determine whether he is Rh-positive. If the father is Rh-positive, the mother's blood will be checked for antibodies against the Rh factor. A test that demonstrates no antibodies is repeated at week 26 or 27 of the pregnancy. If antibodies are present, treatment is begun.

In cases in which incompatibility is not identified before birth, the baby has recognizable characteristic symptoms such as anemia, hyperbilirubinemia, and hydrops fetalis. The blood incompatibility is uncovered through blood tests such as the Coombs test, which measures the level of maternal antibodies attached to the baby's red blood cells. Other blood tests reveal anemia, abnormal blood counts, and high levels of bilirubin.

Treatment

When a mother has antibodies against her unborn infant's blood, the pregnancy is watched very carefully. The antibodies are monitored and if levels increase, **amniocentesis**, fetal umbilical cord blood sampling, and **ultrasound** are used to assess any effects on the baby. Trouble is indicated by high levels of bilirubin in the amniotic fluid or baby's blood, or if the ultrasound reveals hydrops fetalis. If the baby is in danger, and the pregnancy is at least 32–34 weeks along, labor is induced. Under 32 weeks, the baby is given blood transfusions while still in the mother's uterus.

There are two techniques that are used to deliver a blood **transfusion** to a baby before birth. In the first, a needle is inserted through the mother's abdomen and uterus, and into the baby's abdomen. Red blood cells injected into the baby's abdominal cavity are absorbed into its bloodstream. In early pregnancy or if the baby's bilirubin levels are gravely high, cordocentesis is performed. This procedure involves sliding a very fine needle through the mother's abdomen and, guided by ultrasound, into a vein in the umbilical cord to inject red blood cells directly into the baby's bloodstream.

After birth, the severity of the baby's symptoms are assessed. One or more transfusions may be necessary to treat anemia, hyperbilirubinemia, and bleeding. Hyperbilirubinemia is also treated with **phototherapy**, a treatment in which the baby is placed under a special light. This light causes changes in how the bilirubin molecule is shaped, which makes it easier to excrete. The baby may also receive oxygen and intravenous fluids containing electrolytes or drugs to treat other symptoms.

Prognosis

In many cases of blood type incompatibility, the symptoms of erythroblastosis fetalis are prevented with careful monitoring and blood type screening. Treatment of minor symptoms is typically successful and the baby will not develop long-term problems.

Nevertheless, erythroblastosis is a very serious condition for approximately 4,000 babies annually. In about 15% of cases, the baby is severely affected and dies before birth. Babies who survive pregnancy may develop kernicterus, which can lead to deafness, speech problems, **cerebral palsy**, or intellectual disabilities (ID). Extended hydrops fetalis can inhibit lung growth and contribute to **heart failure**. These serious complications are life threatening, but with good medical treatment, the fatality rate is very low. According to the U.S. Centers for Disease Control and Prevention, there were 21 infant deaths in the United States during 1996 that were attributable to hemolytic disease (erythroblastosis fetalis) and jaundice.

Prevention

With any pregnancy, whether it results in a live birth, **miscarriage**, **stillbirth**, or abortion, blood typing is a universal precaution against blood compatibility disease. Blood types cannot be changed, but adequate forewarning allows precautions and treatments that limit the danger to unborn babies.

If an Rh-negative woman gives birth to an Rh-positive baby, she is given an injection of immunoglobulin G, a type of antibody protein, within 72 hours of the birth. The immunoglobulin destroys any fetal blood cells in her bloodstream before her immune system can react to them. In cases where this precaution is not taken, antibodies are created and future pregnancies may be complicated.

WWW.BOOKBAZ.IR

KEY TERMS

Amniocentesis—A procedure in which a needle is inserted through a pregnant woman's abdomen and into her uterus to withdraw a small sample of amniotic fluid. The amniotic fluid can be examined for sign of disease or other problems afflicting the fetus.

Amniotic fluid—The fluid that surrounds a fetus in the uterus.

Anemia—A condition in which there is an abnormally low number of red blood cells in the bloodstream. Major symptoms are paleness, shortness of breath, unusually fast or strong heart beats, and tiredness.

Antibody—A protein molecule produced by the immune system in response to a protein that is not recognized as belonging in the body.

Antigen—A protein that can elicit an immune response in the form of antibody formation. With regard to red blood cells, the major antigens are A, B, O, and the Rh factor.

Bilirubin—A yellow-colored end-product of hemoglobin degradation. It is normally present at very low levels in the bloodstream; at high levels, it produces jaundice.

Cordocentesis—A procedure for delivering a blood transfusion to a fetus. It involves a fine needle being threaded through a pregnant woman's abdomen and into the umbilical cord with the aid of ultrasound imaging.

Hemoglobin—A molecule in red blood cells that transports oxygen and gives the cells their characteristic color.

Hydrops fetalis—A condition in which a fetus or newborn baby accumulates fluids, causing swollen arms and legs and impaired breathing.

Hyperbilirubinemia—A condition in which bilirubin accumulates to abnormally high levels in the bloodstream

Placenta—A protective membrane that surrounds and protects the fetus during pregnancy.

Platelet—A blood factor that is important in forming blood clots.

Rh factor—An antigen that is found on the red blood cells of most people. If it is present, the blood type is referred to as Rh-positive; if absent, the blood type is Rh-negative.

Erythrocyte sedimentation rate

Definition

The erythrocyte sedimentation rate (ESR), or sedimentation rate (sed rate), is a measure of the settling of red blood cells in a tube of blood during a specified period of time. The rate is an indication of inflammation and increases in many diseases.

Purpose

ESR is increased in rheumatoid diseases, most infections, and in cancer. An advanced rate does not diagnose a specific disease, but it does indicate that an underlying disease may be present.

A physician can use ESR to monitor a person with an associated disease. When the disease worsens, the ESR may increase; when the disease improves, the ESR may decrease. The ESR does not always follow the course of cancer.

ESR is called an acute-phase reactant test, meaning that it reacts to acute conditions in the body, such as infection or **trauma**. The rate increase follows a rise in temperature and increase in **white blood cell count**, peaks after several days, and usually lasts longer than the elevated temperature or increased white blood cell count.

Description

The ESR test is a simple test dating back to the ancient Greeks. A specific amount of diluted, unclotted blood is placed in a special narrow tube and left undisturbed for a specified amount of time. The red cells settle towards the bottom of the tube, and the pale yellow liquid (plasma) rises to the top. After the specified time has elapsed, measurements are taken of the

KEY TERMS

Acute phase reactant—A substance in the blood that increases as a response to an acute conditions such as infection, injury, tissue destruction, some cancers, burns, surgery, or trauma.

Rouleaux—The stacking up of red blood cells, caused by extra or abnormal proteins in the blood that decrease the normal distance red cells maintain between each other.

distance the red cells traveled to settle at the bottom of the tube. Methods used include the Westergren, the modified Westergren and the Wintrobe methods. Each method produces slightly different results. Most laboratories use the Westergren or modified Westergren method.

Normally, red cells do not settle far toward the bottom of the tube. Many diseases make extra or abnormal proteins that cause the red cells to move close together, stack up, and form a column (rouleaux). In a group, red cells are heavier and fall faster. The faster they fall, the further they settle, and the higher the ESR.

The ESR test is covered by insurance when medically necessary. Results are usually available the same or following day.

Preparation

This test requires about 5mL of blood. A healthcare worker ties a tourniquet on the patient's upper arm, locates a vein in the inner elbow region, and inserts a needle into that vein. Vacuum action draws the blood through the needle into an attached tube. Collection of the sample takes only a few minutes.

Aftercare

Discomfort or bruising may occur at the puncture site. Pressure applied to the puncture site until the bleeding stops reduces bruising. Warm packs to the puncture site relieve discomfort. The patient may feel dizzy or faint.

Risks

There are no major risks associated with this blood test.

Results

A normal value does not rule out disease. Normal values for the Westergren method are:

- Newborns (male or female): 0–2 mm/hr
- Females less than 50 years old: 0–25 mm/hr
- Males less than 50 years old: 0–15 mm/hr
- Females 50 years and older: 0–30 mm/hr
- Males 50 years and older: 0–20 mm/hr

Abnormal results

The highest ESR levels are usually seen in a cancer of a certain type of white blood cell (**multiple myeloma**) and rheumatoid disease, such as **rheumatoid arthritis**. Many other diseases also increase the ESR: infection, **kidney disease**, anemia, diseases involving white blood cells, cancer, and autoimmune and inflammatory diseases.

Any disease that changes the shape and size of red blood cells decreases the ESR. Distorted cells, such as with **sickle cell disease**, do not stack, and consequently do not settle far, even in the presence of an ESR-associated disease. Diseases that cause the body to make less protein or extra red blood cells also decrease the ESR.

Some medications, including anticonvulsants, **oral contraceptives**, and others may cause an increase in the ESR. Drugs such as cortisone and quinine may cause a decrease in ESR values.

Erythromycins and macrolide antibiotics

Definition

Macrolides are **antibiotics** that kill bacteria or prevent their growth.

WWW.BOOKBAZ.IR

KEY TERMS

Bacteria—Organisms that can only be seen under a microscope.

Bronchitis—Infection of the air passages in the lungs.

Gonorrhea—A sexually transmitted infection with fever and a pussy penile discharge in males and abdominal pain and vaginal discharge in females.

Pneumonia—Infection of the lungs caused by bacteria, viruses, or chemical irritants.

Sinus—Air-filled cavities in the bones of the skull.

Purpose

Macrolides are used to treat bacterial infections in various sites:

- middle and inner ear
- eyes
- sinuses
- tonsils
- throat and larynx (voice box)
- lungs (pneumonia and bronchitis)
- skin (infected eczema, acne, psoriasis)
- genitalia, sexually transmitted diseases (Chlamydia, gonorrhea)

These antibiotics are used to prevent infections prior to dental and other procedures for patients at risk for developing infections of the heart valves (**endocarditis**).

Macrolide antibiotics can be used as alternatives to penicillin for people with penicillin **allergies**.

These antibiotics will not cure colds, flu, and other viral infections.

Description

Members of the macrolide antibiotic family include erythromycin (Erythrocin, Ery-C, E-Mycin, azithromycin (Zithromax) and clarithromycin (Biaxin). They are available by prescription as capsules, tablets (including chewable), liquids, and for injection.

Recommended dosage

Dosage depends on the drug used and the reason for its use.

Antibiotics should always be taken exactly as directed, for as long as they are prescribed. Do not stop antibiotics if symptoms begin improving.

Precautions

These drugs should be used with caution by patients with liver or **kidney disease**.

People who have inherited blood disorders, like porphyria, should not take these antibiotics.

Macrolides increase the risk of heart arrhythmia in patients who have prolonged Q-T interval on EKG.

These antibiotics may aggravate muscle weakness in patients with **Myasthenia Gravis**.

ALLERGIES. Anyone who has had unusual reactions to a macrolide antibiotic previously should avoid taking it again.

PREGNANCY. There are no well controlled studies on these antibiotics and **pregnancy**.

BREASTFEEDING. Macrolide antibiotics pass into breast milk, though no specific dangers have been identified.

Side effects

Macrolide antibiotics may widen the Q-T interval on EKG. People who are at risk for developing severe heart **arrhythmias**, or who take drugs that widen the Q-T interval, should avoid taking these antibiotics.

The more common side effects from macrolides include mild **diarrhea**, nausea, **vomiting**, and stomach or abdominal cramps that go away as the body adjusts to the drug.

Less commonly, sore mouth or tongue and vaginal **itching** may occur. These rarely require medical attention.

If these, more serious, side effects occur, seek medical help:

- severe abdominal pain, and continued nausea, vomiting, or diarrhea
- fever
- skin rash, redness, or itching
- unusual tiredness or weakness
- swelling of the lips, face or neck

Interactions

Prescribers need to know the medications their patients take; this class of antibiotics may interact with many drugs.

Food may change the effects of erythromycin and clarithromycin (Biaxin), increasing the risks of side or adverse effects.

Grapefruit juice may increase the absorption of macrolide antibiotics, possibly increasing the possibility of adverse or side effects.

St. John's Wort may decrease blood levels of erythromycin.

The effectiveness of combined **oral contraceptives** may be reduced when macrolide antibiotics are taken. It would be wise to use an additional method of preventing pregnancy for up to seven days after discontinuing these antibiotics.

Taking quinolone antibiotics (Tequin, Levaquin, Avelox) with erythromycin increases the potential for fatal heart arrhythmias.

Macrolide antibiotics increase:

- the risk of fatal heart arrhythmias when taken with medications to treat heart arrhythmias, (Cordarone, Norpace, Tikosyn, Sotalol, Bretylium, and Quinidine).
- the blood-thinning effects of warfarin (Coumadin).
- the adverse, muscle wasting effects of cholesterol-reducing medications (Lipitor, Zocor, Mevacor).
- digoxin toxicity in people who take digoxin (Lanoxin).
- the risk of developing carbamazepine toxicity in people who take carbamazepine (Tegretol) for seizures, schizophrenia , ethanol withdrawal, restless leg syndrome, or post-traumatic stress disorder (PTSD).
- the effects of Colchicine used to treat **Gout**, increasing the risk of toxicity.
- the effects, and toxicity, of ergot drugs used to treat migraine headaches.
- the effects, and toxicity, of pimozide (Orap) and clozapine (Clozaril) used to treat **psychosis**.
- the effects, and toxicity, of verapamil (Calan) used to treat **angina** (heart **pain**) and rapid heartbeats.
- the sedative effects of anti-anxiety medications Buspar and **benzodiazepines** Xanax, Valium, and Halcion.

Taken together, macrolide antibiotics and theophyllines (Choledyl, Theo-Dur and Uniphyl), used to treat chronic **asthma** and asthma-like conditions, adversely effect each other. Theophyllin levels increase in the blood, increasing the chance of toxicity, and macrolide effectiveness is reduced.

Erythropoietin *see* **Cancer therapy, supportive; Immunologic therapies**

Erythropoietin test

Definition

Erythropoietin, also called EPO, is a type of protein called a glycoprotein that is formed mainly in the kidneys to stimulate the production of red blood cells.

Purpose

The erythropoietin (EPO) test is used to determine if hormonal secretion is causing changes in the red blood cells. The test has great value in evaluating low hemoglobin (anemia), and another disorder called polycythemia, in which unusually large numbers of red blood cells are found in the blood. The EPO test is also used to identify kidney tumors and identify or assess **kidney disease** It also may be used to evaluate **abuse** by athletes who believe commercially prepared erythropoietin enhances performance.

Precautions

Not every laboratory is equipped to evaluate EPO, so the reference laboratory (a large commercial lab that does tests for hospitals not equipped to do them) performing the test may require as many as four days to complete the analysis. It should also be noted that EPO values increase in **pregnancy**, in which significantly higher levels are found before the twenty-fourth week.

Description

Erythropoietin is produced primarily in the kidneys but interacts with other factors in the bone marrow to increase red cell production. EPO is unique among the blood cell growth factors, because it is the only one that behaves like a hormone.

WWW.BOOKBAZ.IR

KEY TERMS

Anemia—A condition in which the hemoglobin concentration in the blood is below normal.

Polycythemia vera—A condition characterized by an unusually large number of red blood cells in the blood due to increased production by the bone marrow. Symptoms include headaches, blurred vision, high blood pressure, dizziness, and night sweats.

Secondary polycythemia—Secondary polycythemia occurs when the excess of red blood cells is caused by a condition other than polycythemia vera. For example, when low levels of oxygen in the blood stimulate the bone marrow to produce more red blood cells, as in chronic lung disease.

Erythropoietin acts as the principal regulator in the production of red blood cells (erythrocytes) by controlling the number, the kinds, and the survival of the cells. Because of this ability, it is being investigated for use in cancer patients to prevent anemia (hemoglobin concentration in the blood is lower than normal), or to treat anemia that has been induced by **chemotherapy** and **bone marrow transplantation** (BMT).

The correction of anemia can result in reduced **transfusion** requirements, so the erythropoietin test is used to diagnose anemia, including the anemia of end-stage renal disease. Erythropoietin determination is also valuable in diagnosing a condition known as polycythemia, when increased numbers of red blood cells occur. Levels of erythropoietin are extremely low in **polycythemia vera** but are normal or high in **secondary polycythemia**. It happens rarely, but cysts in the liver or kidneys, as well as tumors in the kidneys or brain, can also produce erythropoietin. Patients with these conditions can have high levels of erythropoietin and may develop secondary polycythemia.

Kidney disease can cause anemia and many patients on **kidney dialysis** will require monthly EPO tests to check their hemoglobin levels.

Some athletes use EPO to enhance performance, as the increased red cell volume adds more oxygen-carrying capacity to the blood. Adverse reactions to this practice can include clotting abnormalities, **headache**, seizures, high blood pressure, nausea, **vomiting**, **diarrhea**, and rash.

Preparation

The EPO test requires a blood sample. The patient is to fast with nothing to eat or drink for at least eight hours before the test. It is also suggested that the patient lie down for 30 minutes before the test.

Risks

Risks for this test are minimal, but may include slight bleeding from the blood-drawing site, **fainting** or feeling lightheaded after venipuncture, and hematoma (blood accumulating under the puncture site).

Results

Reference values vary from laboratory to laboratory, but a general normal range is 11–48 mU/mL (milliunits per milliliter).

Abnormal results

Low levels of EPO are found in anemic patients with inadequate or absent production of erythropoietin. Severe kidney disease may decrease production of EPO, and congenital absence of EPO can occur.

Elevated levels of EPO can be found in some **anemias** when the body tries to overcompensate for reduced blood volume. Elevated levels are also seen in polycythemia, and erythropoietin-secreting tumors.

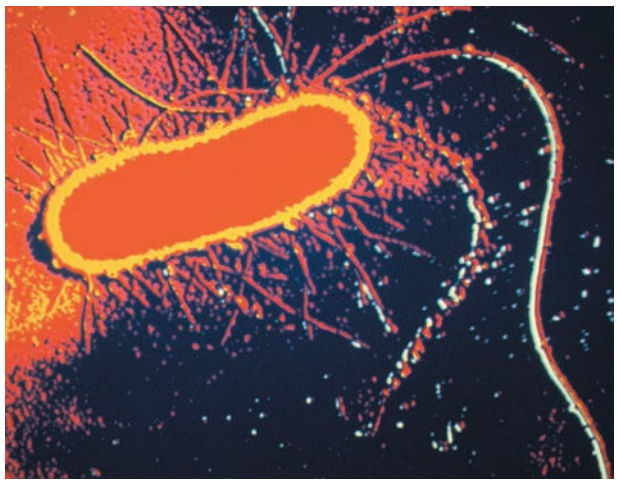
Escherichia coli

Definition

Escherichia coli (*E. coli*) is one of several types of bacteria that normally inhabit the intestine of humans and animals (commensal organism). Some strains of *E. coli* are capable of causing disease under certain conditions when the immune system is compromised, the intestine spills contents into the abdomen or



A magnified image of the E. coli bacterium. *(© Howard Sochurek/Corbis.)*

bloodstream, or when environmental exposure to the organism occurs.

Demographics

E. coli is the most common of its class of bacteria (gram-negative rods) to cause **sepsis**. This type of bacteria is also found in 80% of common urinary-tract infections, as well as many that occur in patients who are hospitalized. *E. coli* neonatal **meningitis** has a mortality rate of 8%. The organism is the leading cause of urinary tract infections in men and in women. The bacterium also causes approximately 30 to 45% of traveler's **diarrhea** in people traveling to Mexico.

Description

E. coli bacteria may give rise to infections in **wounds**, the urinary tract, biliary tract, and abdominal cavity (**peritonitis**). This organism may cause septicemia, neonatal meningitis, infantile **gastroenteritis**, tourist diarrhea, and hemorrhagic diarrhea, and respiratory infections and **pneumonia**. An *E. coli* infection may also arise due to environmental exposure. Infections with this type of bacteria pose a serious threat to **public health** with outbreaks arising from food and water that has been contaminated with human or animal feces or sewage. This type of bacteria has been used as a biological indicator for safety of drinking water since the 1890s. Exposure may occur during hospitalization, resulting in pneumonia in immunocompromised patients or those on a ventilator.

Causes and symptoms

The symptoms of infection and resulting complications are dependent upon the strain of *E. coli* and the site of infection. These bacteria produce toxins that have a wide range of effects. Symptoms caused by some *E. coli* infections range from mild to severe bloody diarrhea, acute abdominal **pain**, **vomiting**, and **fever**. Gastrointestinal complications that can cause *E. coli* infections include **irritable bowel syndrome** (IBS), ischemic **colitis**, **appendicitis**, perforation of the large bowel, and in some instances **gangrene** in the colon. Other known *E. coli*-causing infections include chronic renal failure, **pancreatitis**, and **diabetes mellitus**. Neurological symptoms such as drowsiness, seizure, and **coma** may occur. In infants, *E. coli* infections are present in cases of infantile gastroenteritis and neonatal meningitis.

Strains of *E. coli* that produce diarrhea were initially distinguished by their O (somatic) antigens found on the bacterial surface. Although there is an overlap in characteristics between strains, they may be classified into four main groups; enterohemorrahagic (0157), enteropathogenic (055,0111), enterotoxigenic (06,078), and enteroinvasive (0124,0164).

E.coli O157 (VTEC)

The O157:H7 strain is the member of the group most often associated with a particularly severe form of diarrhea. (The O indicates the somatic antigen, while the H denotes the flagellar antigen, both of which are found on the cell surface of the bacteria.) The bacterium was discovered in 1977, and first reports of infections followed in 1982. *E. coli* O157:H7, as it is frequently referred to by researchers, causes bloody diarrhea in many infected patients. It accounts for about 2% of all cases of diarrhea in the western world, and at least one-third of cases of hemorrhagic colitis, or about 20,000 cases per year.

E. coli O157:H7 is also the most common cause of unique syndromes, known as **hemolytic-uremic syndrome** (HUS) and thrombocytopenic purpura (TTP), which cause kidney failure, **hemolytic anemia**, and **thrombocytopenia**. Infection with this strain of bacteria often subsides without further complications. However, about 5% of people who are infected develop HUS/TTP. This infection also accounts for the majority of episodes of HUS, especially in children.

This strain of bacteria produces a potent toxin called verotoxin, named for the toxin's ability to kill green monkey kidney or "vero" cells. Bacteria that produce verotoxin are referred to as verotoxin-producing *E. coli* (VTEC). The numbers of bacteria that

WWW.BOOKBAZ.IR

are necessary to reproduce infectious levels of bacteria are quite small, estimated at 10–100 viable bacteria. These toxins are lethal for intestinal cells and those that line vessels (endothelial cells), inhibiting protein synthesis and causing cell death. It is believed that the damage to blood vessels results in the formation of clots, which eventually leads to HUS. HUS/TTP is a serious, often fatal, syndrome that has other causes in addition to *E. coli* O157:H7; it is characterized by the breaking up of red blood cells (hemolysis) and kidney failure (uremia). The syndrome occurs most often in the very young and very old.

E. coli O157:H7 is commonly found in cattle and poultry, and outbreaks of disease have been associated with cattle and bovine products. There are reports of contamination from unpasteurized apple juice, hamburger meat, radish sprouts, lettuce, and potatoes, as well as other food sources. Environmental contamination may occur in water drained from cattle pastures or water containing human sewage used for drinking or swimming. Human to human transmission, through contact with fecal matter, has also been identified in daycare centers.

After an incubation period of three to four days on average, watery diarrhea begins, which rapidly progresses to bloody diarrhea in many cases. Nausea, vomiting, and low-grade fever are frequently present. Gastrointestinal symptoms last about one week, and recovery is often spontaneous. Symptomatic infection may occur in about 10% of infected individuals. About 5–10% of individuals, usually at the extremes of age develop HUS/TTP, and ultimately, kidney failure. Patients taking **antibiotics** or medications for gastric acidity may also be at risk. Neurological symptoms can occur as part of HUS/TTP and consist of seizures, **paralysis**, and coma. **Rectal prolapse** may be a complication, and in some cases colitis, appendicitis, perforation of the large bowel, and gangrene in the bowel. Systemically, the most prevalent complications of *E. coli* 157 infections are HUS and TTP.

E. coli non-O157 (VTEC)

These strains of *E. coli* produce verotoxin, but are strains other than O157. There have been as many as 100 different types implicated in the development of disease. Strain OH111 was found to be involved in outbreaks in Australia, Japan, and Italy. The O128, O103, and O55 groups have also been implicated in diarrhea outbreaks. In Britain, cases of infantile gastroenteritis in maternity hospitals and neonatal units have been attributed to the *E. coli* non-0157 group. Many of these organisms have been identified in cattle.

Enterotoxigenic E. coli

Two toxins may be produced by this group, the heat-labile enterotoxin (LT) that can produce enteritis in infants, and a heat stable enterotoxin (ST), the action of which has yet to be determined.

Enteroinvasive E. coli

Some strains of the enteroinvasive *E. coli* have been involved in the development of gastroenteritis in infants. These organisms do not produce an enterotoxin. The cells of the intestine are affected, with the development of symptoms that are typical of a shigellae infection.

Diagnosis

Diagnosis of a specific type of infection is dependent upon the characteristics of the particular strain of the organism.

E. coli O157:H7 (HUS)

This particular strain of *E. coli* is suspected when bloody diarrhea, bloody stools, lack of fever, elevated leukocyte count, and abdominal tenderness are present. Stool cultures are used to tentatively identify the bacteria. Unfortunately, cultures are often negative or inconclusive if done after 48 hours of symptoms. Further tests are usually needed for confirmation of infection. This may include a full blood count, blood film, and tests to determine urea, electrolyte, and LDH (lactate dehydrogenase) levels. Damaged red blood cells and elevated levels of creatinine, urea, and LDH with a drop in **platelet count** may indicate that HUS will develop. Immunomagnetic separation is used for diagnosis as well.

E. coli non-O157 (VTEC)

Diagnosis is often difficult for these types of bacteria, but production of enterohemolysin (Ehly) is used as an indicator. Other diagnostic tests are used to detect verotoxins, including ELISA (enzyme-linked immunosorbent assays), colony immunoblotting, and DNA-based tests.

E. coli 0157 STEC

Methods for detection of this type of bacteria are under development, including culture growth media selective for this organism. Immunomagnetic separation and specific ELISA, latex agglutination tests,

KEY TERMS

Antigen—A substance, usually a protein, that causes the formation of an antibody and reacts specifically with that antibody.

Anti-motility medications—Medications such as loperamide (Imodium), dephenoxylate (Lomotil), or medications containing Codeine or narcotics that decrease the ability of the intestine to contract. This can worsen the condition of a patient with dysentery or colitis.

Colitis—Inflammation of the colon or large intestine, usually causing diarrhea that may be bloody.

Food irradiation methods—A process using radiant energy to kill microorganisms in food, to extend the amount of time in which food can be sold and eaten safely.

Oral Rehydration Solution (ORS)—A liquid preparation developed by the World Health Organization that can decrease fluid loss in persons with diarrhea. Originally developed to be prepared with materials available in the home, commercial preparations have recently come into use.

Urea—Chemical formed during the body's metabolism of nitrogen and normally excreted by the kidney. Urea levels rise in the blood when kidney failure occurs.

colony immunoblot assays, and other immunological-based detection methods are being explored.

Treatment

Traditional

Uncomplicated cases of the *E. coli* O157:H7 infection clear up within 10 days. It is not certain that antibiotics are helpful in treating *E. coli* O157:H7. Antimicrobials that may be administered include doxycycline (Vibramycin), trimethoprim/sulfamethoxazole (Bactrim DS, Septra), **fluoroquinolones** (Cipro), and rifaximin (Xifaxan, RedActiv, Flonorm). **Dehydration** resulting from diarrhea must be treated with either Oral Rehydration Solution (ORS) or intravenous fluids. Anti-motility agents that decrease the intestines' ability to contract, should not be used in any patient with bloody diarrhea. Treatment of HUS, if it develops, involves correction of clotting factors, plasma exchange, and **kidney dialysis**. Blood transfusions may be required. Treatment methods for other *E. coli* infections are similar.

Drugs

Antibiotics are often used in the treatment of *E. coli* infections, but their role is controversial. Some antibiotics may enhance the development of HUS/TTP depending upon their action, as well as the use of anti-diarrhea medications that should be avoided. Treatment with third-generation cephalosporin antibiotics such as ceftriaxone (Rocephin) is indicated for neonatal meningitis.

Antibiotic therapy may be complicated by the presence of antibiotic resistant organisms. These organisms appear to be increasing since the late 1990s and are resistant to the **penicillins** and **cephalosporins** as well as to the fluoroquinolones and gentamicin, which in the past, were reserved to treat only the most serious of infections.

Prognosis

In most cases of O157:H7, symptoms last for about a week and recovery is often spontaneous. Ten percent of individuals with *E. coli* O157:H7 infection develop HUS; 5% of those die of the disease. Some who recover from HUS are left with some degree of kidney damage and possibly irritable bowel syndrome. Additionally, there is a possibility of chronic *E. coli* infection.

Infants who develop *E. coli* infections may be permanently affected. Gastroenteritis may leave the child with **lactose intolerance**. Neonates developing meningitis from *E. coli* strains have a high morbidity and mortality rate, with most surviving infants demonstrating permanent developmental or neurological aftereffects.

Prevention

Thorough cooking of all meat and poultry products and adhering to proper food preparation is the most effective way to avoid infection. More studies are needed to determine the appropriate safety margins for killing these bacteria. Food irradiation methods are also being developed to sanitize food. The enforcement of regulations for meat production and water are critical. Steam pasteurization is used in the United States and is being explored in other countries. Vaccinations to *E. coli* 0157 are under development, as are medications aimed at limiting the effects of the verotoxin.

Prevention of *E. coli* gastroenteritis in infants is best achieved by **breastfeeding**. Breast milk contains antibodies that combat the infection. For bottle-fed infants, care should be taken in the preparation of the

WWW.BOOKBAZ.IR

milk and bottles. Good hygiene of the umbilical cord area is important. Keeping this area clean and dry may reduce infection.

Esophageal atresia

Definition

Esophageal atresia is a serious birth defect in which the esophagus, the long tube that connects the mouth to the stomach, is segmented and closed off at any point. This condition usually occurs with **tracheoesophageal fistula**, a condition in which the esophagus is improperly attached to the trachea, the nearby tube that connects the nasal area to the lungs. Esophageal atresia occurs in approximately 1 in 4,000 live births.

Description

Failure of an unborn child (fetus) to develop properly results in **birth defects**. Many of these defects involve organs that do not function, or function only incidentally, before birth, and, as a result, go undetected until the baby is born. In this case, the digestive tract is unnecessary for fetal growth, since all **nutrition** comes from the mother through the placenta and umbilical cord.

During fetal development, the esophagus and the trachea arise from the same original tissue. Normally, the two tubes would form separately (differentiate); however, in cases of esphageal atresia and tracheoesophageal fistulas, they do not, resulting in various malformed configurations. The most common configuration is the "C" type, in which the upper part of the esophagus abruptly ends in a blind pouch, while the lower part attaches itself to the trachea. This configuration occurs in 85–90% of cases. Esophageal atresia without involvement of the trachea occurs in only 8% of cases.

Causes and symptoms

The cause of esophageal atresia, like that of most birth defects, is unknown.

An infant born with this defect will at first appear all right, swallowing normally. However, the blind pouch will begin to fill with mucus and saliva that would normally pass through the esophagus to the stomach. These secretions back up into the mouth and nasal area, causing the baby to drool excessively. When fed, the baby will also immediately regurgitate what he or she has eaten. **Choking** and coughing may also occur as the baby breaths in the fluid backing up from the esophagus. Aspiration **pneumonia**, an infection of the respiratory system caused by inhalation of the contents of the digestive tract, may also develop.

Diagnosis

Physicians who suspect esophageal atresia after being presented with the above symptoms diagnose the condition using x-ray imaging or by passing a catheter through the nose and into the esophagus. Esophageal atresia is indicated if the catheter hits an obstruction 4–5 in (10–13 cm) from the nostrils.

Treatment

Infants with esophageal atresia are unlikely to survive without surgery to reconnect the esophagus. The procedure is done as soon as possible; however, **prematurity**, the presence of other birth defects, or complications of apiration pneumonia may delay surgery. Once diagnosed, the baby will be fed intravenously until he or she has recovered sufficiently from the operation. Mucus and saliva will also be continuously removed via a catheter until recovery has occured. When surgery is performed, the esophagus is reconnected and, if neccessary, separated from the

KEY TERMS

Fetal—Refers to the fetus, also known in the first two months after conception as an embryo.

Fistula—Unnatural connection between two hollow organs or one organ and the outside.

trachea. If the two ends of the esophagus are too far apart to be reattached, tissue from the large intestine is used to join them.

Prognosis

Surgery to correct esophageal atresia is usually successful. Post-operative complications may include difficulty swallowing, since the esophagus may not contract efficiently, and gastrointestinal reflux, in which the acidic contents of stomach back up into the lower part of the esophagus, possibly causing **ulcers**.

Esophageal cancer

Definition

Esophageal cancer is a malignancy that develops in tissues of the hollow, muscular canal (esophagus) along which food and liquid travel from the throat to the stomach.

Description

Esophageal cancer usually originates in the inner layers of the lining of the esophagus and grows outward. In time, the tumor can obstruct the passage of food and liquid, making swallowing painful and difficult. Since most patients are not diagnosed until the late stages of the disease, esophageal cancer is associated with poor quality of life and low survival rates.

Squamous cell carcinoma is the most common type of esophageal cancer, accounting for 95% of all esophageal cancers worldwide. The esophagus is normally lined with thin, flat squamous cells that resemble tiny roof **shingles**. Squamous cell carcinoma can develop at any point along the esophagus but is most common in the middle portion.

Adenocarcinoma has surpassed squamous cell carcinoma as the most common type of esophageal cancer in the United States. Adenocarcinoma originates in glandular tissue not normally present in the lining of the esophagus. Before adenocarcinoma can develop, glandular cells must replace a section of squamous cells. This occurs in Barrett's esophagus, a precancerous condition in which chronic acid reflux from the stomach stimulates a transformation in cell type in the lower portion of the esophagus.

A very small fraction of esophageal cancers are melanomas, **sarcomas**, or lymphomas.

There is great variability in the incidence of esophageal cancer with regard to geography, ethnicity, and gender. The overall incidence is increasing. About 13,000 new cases of esophageal cancer are diagnosed in the United States each year. During the same 12-month period, 12,000 people die of this disease. It strikes between five and ten North Americans per 100,000. In some areas of China the cancer is endemic.

Squamous cell carcinoma usually occurs in the sixth or seventh decade of life, with a greater incidence in African-Americans than in others. Adenocarcinoma develops earlier and is much more common in white patients. In general, esophageal cancer occurs more frequently in men than in women.

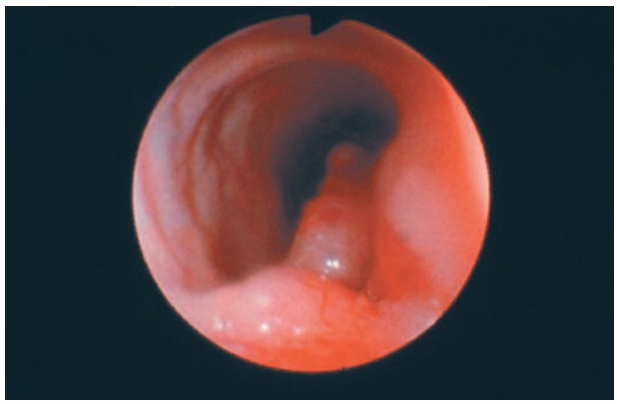
Causes and symptoms

The exact cause of esophageal cancer is unknown, although many investigators believe that chronic irritation of the esophagus is a major culprit. Most of the identified risk factors represent a form of chronic irritation. However, the wide variance in the distribution of esophageal cancer among different demographic groups raises the possibility that genetic factors also play a role.

Several risk factors are associated with esophageal cancer.

- Tobacco and alcohol consumption are the major risk factors, especially for squamous cell carcinoma. Smoking and alcohol abuse each increase the risk of squamous cell carcinoma by five-fold. The effects of the two are synergistic, in that the combination of smoking and alchohol increases the risk by 25- to 100-fold. It is estimated that drinking about 13 ounces of alcohol every day for an extended period of

WWW.BOOKBAZ.IR



A close-up view of a cancerous esophageal tumor. *(Custom Medical Stock Photo, Inc.)*

time raises the risk of developing esophageal cancer by 18%. That likelihood increases to 44% in individuals who also smoke one or two packs of cigarettes a day. Smokeless tobacco also increases the risk for esophageal cancer.

- Gastroesophageal reflux is a condition in which acid from the stomach refluxes backwards into the lower portion of the esophagus, sometimes causing symptoms of heartburn. In some cases of gastroesophageal reflux, the chronic exposure to acid causes the inner lining of the lower esophagus to change from squamous cells to glandular cells. This is called Barrett's esophagus. Patients with Barrett's esophagus are roughly 30 to 40 times more likely than the general population to develop adenocarcinoma of the esophagus.
- A diet low in fruits, vegetables, zinc, riboflavin, and other vitamins can increase risk of developing to esophageal cancer.
- Caustic injury to the esophagus inflicted by swallowing lye or other substances that damage esophageal cells can lead to the development of squamous cell esophageal cancer in later life.
- Achalasia is a condition in which the lower esophageal sphincter (muscle) cannot relax enough to let food pass into the stomach. Squamous cell esophageal cancer develops in about 6% of patients with achalasia.
- Tylosis is a rare inherited disease characterized by excess skin on the palms and soles. Affected patients have a much higher probability of developing esophageal cancer than the general population. They should have regular screenings to detect the disease in its early, most curable stages.
- Esophageal webs, which are protrusions of tissue into the esophagus, and diverticula, which are outpouchings of the wall of the esophagus, are associated with a higher incidence of esophageal cancer.

Symptoms

Unfortunately, symptoms generally do not appear until the tumor has grown so large that the patient cannot be cured. Dysphagia (trouble swallowing or a sensation of having food stuck in the throat or chest) is the most common symptom. Swallowing problems may occur occasionally at first, and patients often react by eating more slowly and chewing their food more carefully and, as the tumor grows, switching to soft foods or a liquid diet. Without treatment, the tumor will eventually prevent even liquid from passing into the stomach. A sensation of burning or slight mid-chest pressure is a rare, often-disregarded symptom of esophageal cancer. Painful swallowing is usually a symptom of a large tumor obstructing the opening of the esophagus. It can lead to regurgitation of food, weight loss, physical wasting, and **malnutrition**. Anyone who has trouble swallowing, loses a significant amount of weight without dieting, or cannot eat solid food because it is too painful to swallow should see a doctor.

Diagnosis

A barium swallow is usually the first test performed on a patient whose symptoms suggest esophageal cancer. After the patient swallows a small amount of barium, a series of x rays can highlight any bumps or flat raised areas on the normally smooth surface of the esophageal wall. It can also detect large, irregular areas that narrow the esophagus in patients with advanced cancer, but it cannot provide information about disease that has spread beyond the esophagus. A double contrast study is a barium swallow with air blown into the esophagus to improve the way the barium coats the esophageal lining. **Endoscopy** is a diagnostic procedure in which a thin lighted tube (endoscope) is passed through the mouth, down the throat, and into the esophagus. Cells that appear abnormal are removed for biopsy. Once a diagnosis of esophageal cancer has been confirmed through biopsy, staging tests are performed to determine whether the disease has spread (metastasized) to tissues or organs near the original tumor or in other parts of the body. These tests may include computed tomography, **endoscopic ultrasound**,

thoracoscopy, **laparoscopy**, and **positron emission tomography**.

Treatment

Treatment for esophageal cancer is determined by the stage of the disease and the patient's general health. The most important distinction to make is whether the cancer is curable. If the cancer is in the early stages, cure may be possible. If the cancer is advanced or if the patient will not tolerate major surgery, treatment is usually directed at palliation (relief of symptoms only) instead of cure.

Staging

Stage 0 is the earliest stage of the disease. Cancer cells are confined to the innermost lining of the esophagus. Stage I esophageal cancer has spread slightly deeper, but still has not extended to nearby tissues, lymph nodes, or other organs. In Stage IIA, cancer has invaded the thick, muscular layer of the esophagus that propels food into the stomach and may involve connective tissue covering the outside of the esophagus. In Stage IIB, cancer has spread to lymph nodes near the esophagus and may have invaded deeper layers of esophageal tissue. Stage III esophageal cancer has spread to tissues or lymph nodes near the esophagus or to the trachea (windpipe) or other organs near the esophagus. Stage IV cancer has spread to distant organs like the liver, bones, and brain. Recurrent esophageal cancer is disease that develops in the esophagus or another part of the body after initial treatment.

Surgery

The most common operations for the treatment of esophageal cancer are esophagectomy and esophagogastrectomy. Esophagectomy is the removal of the cancerous part of the esophagus and nearby lymph nodes. This procedure is performed only on patients with very early cancer that has not spread to the stomach. Esophagogastrectomy is the removal of the cancerous part of the esophagus, nearby lymph nodes, and the upper part of the stomach. The resected esophagus is replaced with the stomach or parts of intestine so the patient can swallow. These procedures can significantly relieve symptoms and improve the nutritional status of more than 80% of patients with dysphagia. Although surgery can cure some patients whose disease has not spread beyond the esophagus, but more than 75% of esophageal cancers have spread to other organs before being diagnosed. Less extensive surgical procedures can be used for palliation.

Chemotherapy

Oral or intravenous **chemotherapy** alone will not cure esophageal cancer, but pre-operative treatments can shrink tumors and increase the probability that cancer can be surgically eradicated. Palliative chemotherapy can relieve symptoms of advanced cancer but will not alter the outcome of the disease.

Radiation

External beam or internal radiation, delivered by machine or implanted near cancer cells inside the body, is only rarely used as the primary form of treatment. Post-operative radiation is sometimes used to kill cancer cells that could not be surgically removed. Palliative radiation is effective in relieving dysphagia in patients who cannot be cured. However, radiation is most useful when combined with chemotherapy as either the definitive treatment or preoperative treatment.

Palliation

In addition to surgery, chemotherapy, and radiation, other palliative measures can provide symptomatic relief. Dilatation of the narrowed portion of the esophagus with soft tubes can provide short-term relief of dysphagia. Placement of a flexible, self-expanding stent within the narrowed portion is also useful in allowing more food intake.

Follow-up treatments

Regular barium swallows and other imaging studies are necessary to detect recurrence or spread of disease or new tumor development.

Alternatives

Photodynamic therapy (PDT) involves intravenously injecting a drug that is absorbed by cancer cells and kills them after they are exposed to specific laser beams. PDT can be used for palliation, but it also cured some early esophageal cancers during preliminary studies. Researchers are comparing its benefits with those of more established therapies.

Endoscopic laser therapy involves delivering short, powerful laser treatments to the tumor through an endoscope. It can improve dysphagia, but multiple treatments are required, and the benefit is seldom long-lasting.

WWW.BOOKBAZ.IR

KEY TERMS

Computed tomography—A radiology test by which images of cross-sectional planes of the body are obtained.

Endoscopic ultrasound—A radiology test utilizing high frequency sound waves, conducted via an endoscope.

Laparoscopy—Examination of the contents of the abdomen through a thin, lighted tube passed through a small incision.

Positron emission tomography—A radiology test by which images of cross-sectional planes of the body are obtained, utilizing the properties of the positron. The positron is a subatomic particle of equal mass to the electron, but of opposite charge.

Synergistic—The combined action of two or more processes is greater than the sum of each acting separately.

Thoracoscopy—Examination of the contents of the chest through a thin, lighted tube passed through a small incision.

Prognosis

Since most patients are diagnosed when the cancer has spread to lymph nodes or other structures, the prognosis for esophageal cancer is poor. Generally, no more than half of all patients are candidates for curative treatment. Even if cure is attempted, the cancer can recur.

Prevention

There is no known way to prevent esophageal cancer.

Esophageal disorders

Definition

The esophagus is a tube that connects the back of the mouth to the stomach. Abnormalities of the esophagus generally fall into one of four categories: structural abnormalities, motility disorders, inflammatory disorders, and malignancies.

Description

The main function of the esophagus is to move food from the back of the mouth to the stomach. The adult esophagus is about 10 in (25 cm) long. It consists of a layer of cells that secretes mucus and two layers of muscle, one circular and one longitudinal. This combination of muscles allows the esophagus to contract and propel food from the mouth the stomach. This rhythmic contraction is called peristalsis. At the end of the esophagus nearest the mouth is a ring of muscle called the upper esophageal sphincter (UES). A similar muscular ring called the lower esophageal sphincter (LES) is found 1–1.5 in (2–4 cm) above the point where the esophagus enters the stomach. The LES contracts to prevent the contents of the stomach from backflowing into the lower end of the esophagus.

Structural abnormalities

Structural abnormalities of the esophagus can be either congenital or acquired. Congenital abnormalities occur in about 1 of every 3,000–5,000 births. The two most common congenital esophageal abnormalities are **esophageal atresia** (EA) and **tracheoesophageal fistula** (TEF).

EA is a condition in which the esophagus is interrupted and the portion of the tube near the mouth is not connected to the portion that goes into the stomach. Usually the upper part of the tube ends in a blind pouch. This creates a life-threatening condition for the newborn who is unable to eat.

TEF is a condition in which the esophagus is connected to the trachea (windpipe). The trachea and the esophagus lie parallel to each other in the neck. Sometimes during fetal development, a connection called a **fistula** develops between these two tubes. This allows food to enter the trachea and be inhaled into the lungs causing a life-threatening condition called aspiration **pneumonia**. Often TEF and EA are present in the same infant. Both these conditions must be surgically corrected for the infant to survive.

Other, less common congenital structural abnormalities include webs, stenosis, cysts, and diverticula.

Webs are thin membranes that lie across the esophagus and cause a partial obstruction. Stenosis is the abnormal reduction in the diameter of the esophagus due to thickening of the esophageal wall. Diverticula are pouches of tissue that extend off the esophagus. Both diverticula and stenosis can be either congenital or acquired later in life.

Acquired structural abnormalities of the esophagus include Schatzki ring and **hiatal hernia**. Schatzki ring, sometimes called a **lower esophageal ring**, is a circular band of tissue located where the esophagus empties into the stomach. This ring is found in 6–14% of individuals, and for most people the presence of this ring does not create symptoms. Schatzki ring is found equally in all races and in both men and women. Schatzki rings that cause symptoms usually occur in middle age individuals. The ring can cause intermittent problems swallowing food or food impaction where the esophagus enters the stomach.

The esophagus passes a gap in the diaphragm called the diaphragmatic hiatus in order to reach the stomach. Hiatal **hernia** (also called hiatus hernia) is a condition that occurs when a portion of the stomach pushes up through this gap next to the esophagus. Although a hiatal hernia is not a direct structural abnormality of the esophagus, it is associated with **gastroesophageal reflux disease** (GERD) or **heartburn** in which the acidic stomach contents backflow into the lower part of the esophagus and erode the cell lining. Hiatal hernia is very common and often causes no symptoms.

Lacerations, tears, and ruptures of the esophagus, known as **Mallory-Weiss syndrome** and Boerhaave syndrome, are life-threatening disorders. Mallory-Weiss syndrome usually occurs in alcoholics. In both conditions, tears result from **vomiting** and retching. The resulting bleeding creates a medical emergency that can be fatal.

Motility abnormalities

Motility abnormalities create difficulty in swallowing, called dysphagia. Dysphagia is a symptom of several esophageal motility disorders as well as several obstructive disorders such as esophageal webs or Schatzki ring.

Achalasia is an esophageal motility disorder caused by uncoordinated contractions of the two muscular layers that make up the esophagus. Because muscular contractions are disorganized, peristalsis and the orderly movement of food down the esophagus does not occur. In addition, with achalasia the lower esophageal sphincter remains contracted when food is present in the esophagus which prevents the food from entering the stomach. This causes the esophagus to bulge above the LES, a condition called megaesophagus.

Achalasia is caused by destruction of some of the nerve cells that control muscular contraction of the esophagus. This disorder generally begins in young adults and becomes progressively worse as the individual ages. Individuals with achalasia also have a higher risk of developing **esophageal cancer** at an earlier than usual age.

Individuals can also develop esophageal motility disorders secondary to other muscle diseases. **Scleroderma** is a disorder in which smooth muscle begins to atrophy. The smooth muscle in the esophagus can be affected just like other smooth muscle in the body, making swallowing difficult. Scleroderma esophagus is also associated with GERD and increased risk of cancer of the esophagus. Other conditions such as **diabetes mellitus**, **alcoholism**, and some psychiatric disorders can also produce secondary esophageal motility disorders.

Inflammatory disorders

Inflammatory esophageal disorders fall under the general name of esophagitis. Esophagitis causes the esophagus to become swollen and the lining of the esophagus becomes eroded and sore. It is present in about 5% of the population in the United States. There are four main types of esophagitis: reflux, infection, corrosive, and radiation. Reflux esophagitis is caused by GERD when the lower esophageal sphincter does not close tightly and the acidic contents of the stomach enter esophagus. Infectious esophagitis can be caused by fungal, viral, or bacterial infections. Infectious esophagitis occurs frequently in individuals with compromised immune systems, such as those with **AIDS** or leukemia. Corrosive esophagitis occurs when an individual either intentionally or accidentally swallows harsh chemicals such as lye. Radiation esophagitis is a complication of radiation treatments for cancer of the esophagus or lung.

Malignancies

Barrett's esophagus is a pre-cancerous condition that has a high risk of developing into esophageal cancer. It is found most commonly in white males in their 50s and 60s and is usually associated with years of chronic GERD.

Cancers of the esophagus tend to be aggressive and have poor outcomes. Adenocarcinoma is the primary cancer of the esophagus.

WWW.BOOKBAZ.IR

Causes and symptoms

The causes of esophageal disorders depend on the type of disorder. Congenital defects are caused by errors in development. It is not clear why some structural disorders, such as Schatzki ring and hiatal hernia, occur. Many more people have these defects than develop symptoms or seek medical care, so that the presence of these asymptomatic structural defects is found only during autopsies. Other individuals develop symptoms that require medical attention. **Obesity** and advancing age are thought to be contributing factors in developing symptoms.

Achalasia is caused by death of nerve cells that control the muscles that make peristalsis possible. These nerve cells are destroyed by T cells that are part of the body's immune system. It is not clear what triggers these T cells to attack inappropriately. Difficulty swallowing develops slowly, usually beginning in young adults, although the disorder can occur in children. As nerve control is lost, the LES fails to relax, preventing food from entering the stomach. As a result, the lower part of the esophagus becomes stretched creating a condition called megaesophagus. At night, food is often regurgitated and can be inhaled into the lungs, creating the risk of aspiration pneumonia. Achalasia can also be caused by Chagas' disease, a disease rare in North America, but common in Central and South America. Individuals with achalasia are also at higher risk to develop esophageal cancer, esophageal infections, and esophageal rupture.

Inflammatory esophagitis is most often caused by GERD. Infectious esophagitis can be caused by fungi, usually *Candida albicans*, bacteria, or viruses. **Fungal infections** usually occur in individuals who have diabetes, a weakened immune system, or who are taking **antibiotics**. Antibiotics change the balance of naturally occurring bacteria in the esophagus and allow fungi, which are normally present in the digestive tract, to grow unchecked. The most common causes of viral esophagitis are cytomegalovirus (CMV) and *Herpes simplex*. These are usually opportunistic infections in individuals with HIV/AIDS.

Corrosive esophagitis is usually caused by swallowing harsh chemicals, but it can also be caused by certain medications. Radiation esophagus is a side effect of **radiation therapy** for cancer.

Diagnosis

EA and TEF can sometimes be diagnosed in fetal ultrasounds before birth. If not, these defects become obvious soon after birth, because the infant is unable to eat. The inability to pass a tube from the mouth to the stomach is a definite diagnosis for EA. TEF can be detected through x rays.

A barium swallow x ray with video is the basic method of diagnosing most esophageal disorders. For a barium swallow x ray, the individual drinks a barium, a material that coats the esophagus and shows up on x-ray film. A video camera records the passage of the barium down the esophagus in order to detect **swallowing disorders** or pockets and pouches (diverticula) bulging from the esophagus. A barium swallow is also used to detect Schatzki rings.

Upper gastrointestinal **endoscopy** is often used in conjunction with a barium swallow to diagnose esophageal disorders. In an endoscopy, a thin, fiberoptic tube with a tiny camera is inserted into the esophagus. This allows the physician to see the lining of the esophagus. Endoscopes are equipped to take samples (biopsies) of any areas that may appear pre-cancerous or cancerous or to collect samples to test for the organism causing infectious esophagitis.

GERD can often be diagnosed from symptoms such as heartburn and regurgitation. Mallory-Weiss tears and Boerhaave syndrome are difficult to diagnose. Individuals with these disorders are often severely ill and have intense chest **pain** and vomiting, however chest x rays are normal 10–15% of the time. CT scans may be used in conjunction with chest x rays.

Treatment

Surgery is the only treatment for EA and TEF. It is done as soon as possible, based on the condition of the infant and any other **birth defects** that may be present that could affect the surgery.

Schatzki rings and hiatal hernias often cause no or mild symptoms and need no treatment. In severe cases, Schatzki rings are treated with bougienage. In this treatment, a series of tubes of ever-increasing diameter are inserted through the esophagus to stretch the ring. Stretching can also be done with balloon dilation. Surgery is done when no other treatment succeeds in relieving symptoms. Large hiatal hernias can be repaired surgically, but often there is not need for treatment. GERD accompanies many hiatal hernias. GERD can be treated with drugs to block acid production in the stomach (H2 blockers or **proton pump inhibitors**) and changes in diet. In severe cases of GERD stomach surgery may be necessary.

Mallory-Weiss syndrome and Boerhaave syndrome are medical emergencies. The individual is

stabilized and the tear or rupture is repaired surgically. The chance of infection (**sepsis**) is high, so individuals are admitted to intensive care and do not take any food or liquid by mouth for 7–10 days. Hospital stays can last months, and repeated tears are possible.

Achalasia is treated with drugs that relax the smooth muscle and allow the LES to relax and open. When this fails, surgery may be needed. Individuals that are not good candidates for surgery (the elderly or frail) may be treated by injecting botulinum toxin (botox) into the LES to prevent it from closing. The disadvantage of this treatment is its expense and the fact that more than one injection is needed.

Infectious esophagitis is treated by treating the underlying cause of the disease with antifungal, antiviral or antibiotic medications. These can be given either by mouth or intravenously (IV) depending on the severity of the disease.

Malignancies are treated with **chemotherapy** and radiation.

Prognosis

The outcome of treatment depends on the type of disorder, severity, age, and general health of the individual. EA and TEF surgeries are often successful, but infants born with these conditions frequently have other congenital abnormalities that compromise their health.

When needed, treatment for Schatzki rings produces relief of symptoms, but almost always has to be repeated periodically.

Mallory-Weiss and Boerhaave syndromes are often fatal. Thirty to fifty percent of individuals die from these disorders even if they are diagnosed promptly. If diagnosis is delayed, the death rate can be as high as 90%.

Achalasia and scleroderma esophagus are progressive diseases that need continued therapy. They frequently lead to serious weight loss and **malnutrition**.

The outcome for treatment of inflammatory esophagitis depends almost entirely on the success of treating the underlying cause. Where individuals have a weakened immune system, infectious esophagitis can be an ongoing problem. When inflammatory esophagitis is caused by GERD, treatment along with lifestyle modification is usually successful in providing relief.

Esophageal cancers are aggressive and have generally poor outcomes.

KEY TERMS

Atrophy—To wither and become unresponsive.

Congenital—Present at birth.

Diaphragm—A muscle that separates the cavity containing the lungs from the abdomen.

Diverticula—Abnormal pouches of tissue that bulge off the main part of the digestive system.

Peristalsis—A wave of contractions passing through a hollow muscular tube such as the esophagus or intestine.

Prevention

Many symptoms of esophageal disorders can be prevented or alleviated by lifestyle changes that include:

- weight loss to control obesity
- eating slowly and chewing food well
- eating smaller and more frequent meals
- not eating several hours before going to bed
- limiting the use of alcohol and caffeine

Esophageal function tests

Definition

The esophagus is the muscular tube through which food passes on its way from the mouth to the stomach. The main function of the esophagus is to propel food into the stomach. To ensure that food does not move backward—a condition known as reflux—sphincters (constricting ring-shaped muscles) at either end of the esophagus close when the food is not passing through them in a forward direction. Esophageal function tests are used to determine whether the sphincters are working properly.

Purpose

The esophagus has two sets of sphincters at its upper and lower ends. Each of these muscular rings must contract in an exact sequence for swallowing to proceed normally. The upper esophageal sphincter normally stops the contents of the stomach from moving backward into the pharynx and larynx (voice box). The lower esophageal sphincter guards against stomach acid moving upward into the esophagus. The lower sphincter should be tightly closed except to allow food and fluids to enter the stomach.

The three major symptoms occurring with abnormal esophageal function are difficulty with swallowing (dysphagia), **heartburn**, and chest **pain**. Doctors perform a variety of tests to evaluate these symptoms. **Endoscopy**, which is not a test of esophageal function, is often used to determine if the lining of the esophagus has any **ulcers**, tumors, or areas of narrowing (strictures). However, many times endoscopy only shows the doctor if there is an injury to the esophageal lining; it does not always provide information about the cause of the problem. Tests that measure the functioning of the esophagus are sometimes needed in addition to endoscopy. There are three basic types of tests used to assess esophageal function:

- Manometry is used to study the way the muscles of the esophagus contract, and is most useful for investigating dysphagia.
- Esophageal pH monitoring measures changes in the acidity of the esophagus, and is valuable for evaluating patients with heartburn or gastroesophageal reflux disease (GERD).
- X-ray studies are used to investigate dysphagia, either by using a fluoroscope to follow the progress of a barium mixture during the process of swallowing or by using radioactive scanning techniques.

Description

Manometry

This study is designed to measure the pressure changes produced by contraction of the muscular portions of the esophagus. An abnormality in the function of any one of the segments of the esophagus can cause difficulty in swallowing (dysphagia). A manometric examination is most useful in evaluating patients when an endoscopy yields normal results.

During manometry, the patient swallows a thin tube carrying a device that senses changes in pressure in the esophagus. Readings are taken at rest and during the process of swallowing. Medications are sometimes given during the study to aid in the diagnosis. The results are then transmitted to recording equipment. Manometry is most useful in identifying diseases that produce disturbances of motility or contractions of the esophagus. In 2003, a solution containing five drops of peppermint oil in 10 mL of water was found to improve the manometric features of diffuse **esophageal spasm** (DES). The peppermint oil solution eliminated simultaneous esophageal contractions in all patients in the study.

Esophageal pH monitoring

This procedure measures the esophagus' exposure to acid reflux from the stomach. The test is ideal for evaluating recurrent heartburn or **gastroesophageal reflux disease** (GERD). Excessive acid reflux may produce ulcers, or strictures resulting from healed ulcers, in addition to the symptom of heartburn.

Normally, acid from the stomach washes backward into the esophagus in small amounts for short periods of time. The lower esophageal sphincter usually prevents excessive reflux in patients without disease. Spontaneous contractions that increase esophageal emptying and production of saliva also act to prevent damage to the esophagus.

KEY TERMS

Achalasia—Failure of the lower end of the esophagus (or another tubular valve) to open.

Barium—A metallic element used in its sulfate form as a contrast medium for x-ray studies of the digestive tract.

Bolus—A mass of food ready to be swallowed, or a preparation of medicine to be given by mouth or IV all at once rather than gradually.

Cathartic—A medication or other agent that causes the bowels to empty.

Craniopharyngeal achalasia—A swallowing disorder of the throat.

Diffuse esophageal spasm (DES)—An uncommon condition characterized by abnormal simultaneous contractions of the esophagus.

Dysphagia—Difficulty or discomfort in swallowing.

Esophagus—The muscular passageway between the throat and the stomach.

Heartburn—A sensation of warmth or burning behind the breastbone, rising upward toward the neck. It is often caused by stomach acid flowing upward from the stomach into the esophagus.

Hiatal hernia—A condition in which part of the stomach pushes up through the same opening in the diaphragm that the esophagus passes through.

Motility—Ability to move freely or spontaneously. Esophageal motility refers to the ability of the muscle fibers in the tissue of the esophagus to contract in order to push food or other material toward the stomach.

Peristalsis—The wavelike contraction of the muscle fibers in the esophagus and other parts of the digestive tract that pushes food through the system.

Sphincter—A circular band of muscle fibers that constricts or closes a passageway in the body. The esophagus has sphincters at its upper and lower ends.

Researchers have shown that in the esophagus, the presence of acid is damaging only if it lasts over long periods of time. Therefore, esophageal pH monitoring has been designed to monitor the level of acidity over a 24-hour period, usually in the patient's home. In this way, patients are able to maintain their daily routine, document their symptoms, and correlate symptoms with specific activities. During this period, a thin tube with a pH monitor remains in the esophagus to record changes in acidity. After the study, a computer is used to compare the changes with symptoms reported by the patient.

In addition to esophageal pH monitoring, the doctor may perform a Bernstein test (also known as the acid perfusion test) and an acid clearing test. In the Bernstein test, a small quantity of hydrochloric acid (HCl) is directed into the patient's esophagus. If the patient feels pain from the acid, the test is positive for reflux esophagitis. If there is no discomfort, another explanation must be sought for the patient's symptoms. In the acid clearing test, HCl is also directed into the esophagus. This test measures the patient's ability to quickly swallow the acid. If the patient has to swallow more than 10 times to move the acid down the esophagus, he or she has a problem with esophageal motility.

Monitoring of pH levels is usually performed before surgery to confirm the diagnosis and to judge the effects of drug therapy. In 2003, studies showed that integrated esophageal and gastric acidity provided better quantitative measures of esophageal dysfunction in GERD than conventional measurements of pH. This finding may suggest better ways to evaluate the effectiveness of different treatments for GERD.

X-ray tests

X-ray tests of esophageal function fall into two categories: (1) tests performed with barium and a fluoroscope; and (2) those performed with radioactive materials. Studies performed with fluoroscopy are especially useful in identifying structural abnormalities of the esophagus. Sometimes the patient is given a sandwich or marshmallow coated with barium in order to identify the site of an obstruction. Fluoroscopy can diagnose or provide important information about a number of disorders involving esophageal function, including cricopharyngeal **achalasia** (a swallowing disorder of the throat), decreased or reverse peristalsis, and **hiatal hernia**.

During fluoroscopy, the radiologist can observe the passage of material through the esophagus in real time, and also make video recordings. These observations are particularly useful when the swallowing symptoms appear to occur mostly in the upper region of the esophagus. The most common cause of difficulty swallowing is a previous **stroke**, although other diseases of the neuromuscular system (like **myasthenia gravis**) can produce similar symptoms.

WWW.BOOKBAZ.IR

Scans using low-dose radioactive materials are useful because they may demonstrate that food passes more slowly than usual through the esophagus. They can also measure the speed of the bolus' passage. These studies involve swallowing food coated with radioactive material, followed by a nuclear medicine scan. Scans are often used when other methods have failed to make a diagnosis, or if it is necessary to determine the degree of the abnormality.

Preparation

Patients should not eat or drink anything after midnight before an esophageal function test. Many medications affect the esophagus; doses may need to be adjusted or even discontinued prior to testing. Patients must inform their physician of any and all medications they take, including over-the-counter medications and herbal preparations. They must also tell the doctor about any known **allergies**.

Aftercare

No special care is needed after most esophageal function tests. Patients can usually return to their normal daily activities following almost all of these tests.

Risks

Exposure to x rays, especially in the first three months of a woman's **pregnancy**, can be harmful to the fetus. Barium swallows may also cause impaction (hardening) of fecal matter. Additionally, although the tubes passed through the esophagus during some of the esophageal function tests are small and most patients adjust to them quite well, some patients may gag and aspirate (breathe into the lungs rather than passing through the esophagus) some gastric juices.

Results

Normal findings include:

- lower esophageal sphincter pressure, 10–20 mm Hg (millimeters of mercury)
- normal peristaltic waves
- normal size, shape, position, patency, and filling of the esophagus
- negative acid reflux
- acid clearing in fewer than 10 swallows
- negative Bernstein test

Manometry is used to diagnose abnormalities related to contraction or relaxation of the various muscular regions of the esophagus. These studies cannot distinguish whether injury to either the muscle or nerves of the esophagus is producing the abnormal results—only the final effect on esophageal muscle is identified. The results of this test should be interpreted in light of the patient's entire medical history. For example, there are many diseases that affect the relaxation of the lower esophageal sphincter; one such condition is called achalasia, and is a frequent finding in individuals with **Down syndrome**. Achalasia is a type of esophageal motility disorder characterized by the lack of muscular contractions in the lower portion of the esophagus. In addition, the valve at the bottom of the esophagus fails to open and let food into the stomach. This condition results in difficulty eating solid foods and drinking fluids and may become more advanced over time, causing regurgitation and spasm of the chest wall muscles.

Abnormal results of pH tests can confirm symptoms of heartburn or indicate a cause of chest pain (or rarely, swallowing difficulties). The patient's doctor may want to prescribe or change medications based on these results, or even repeat the test using different doses of medication. These studies should be done before surgical treatment of GERD.

X-ray tests can serve to document an abnormality in the esophagus. If the results are negative, other studies may be needed.

Esophageal pouches

Definition

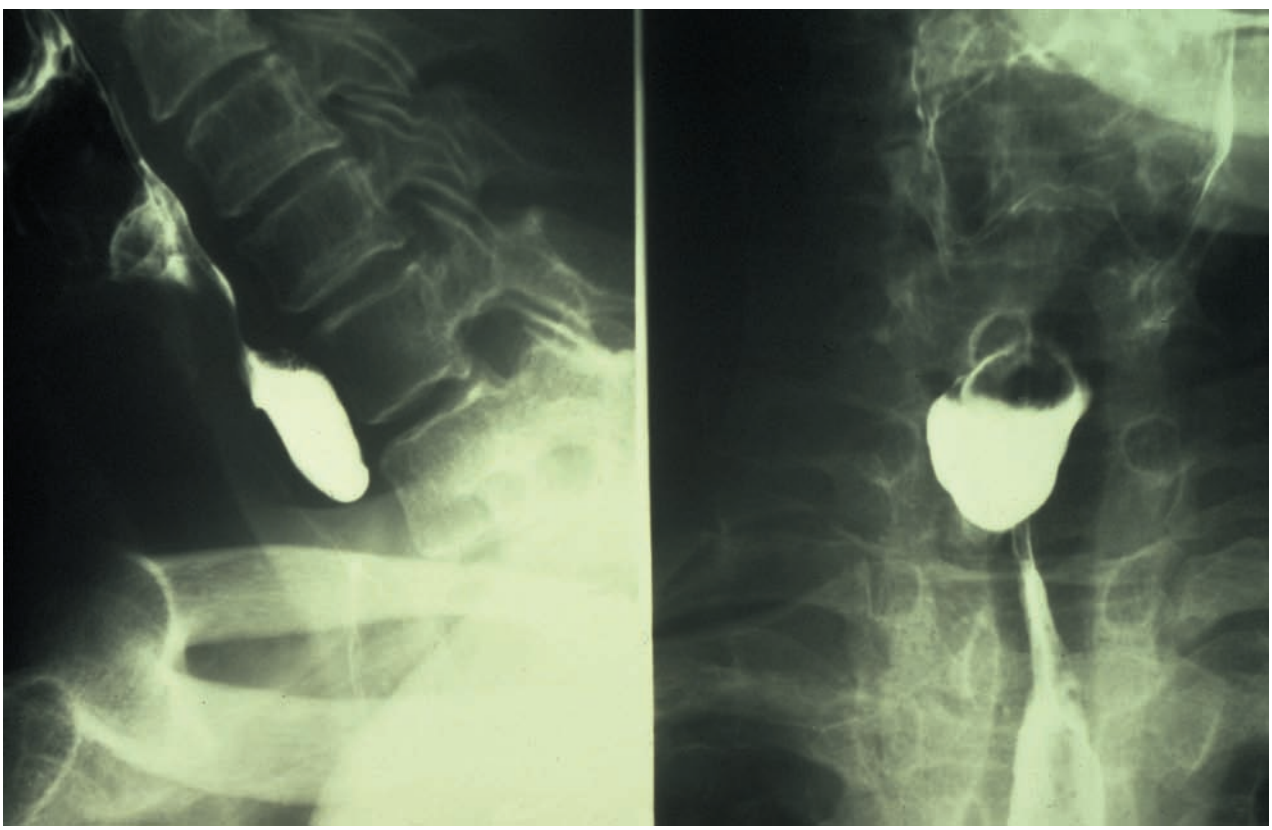
Esophageal pouches, also known as esophageal diverticula, are pocket-like structures formed when the interior space of the esophagus, the tube that connects the mouth to the stomach, protrudes into the walls that surround it.

Description

The esophagus is a muscular tube that propels food into the stomach. A defect in the wall of the esophagus may allow the lining to herniate, creating a space where food can be caught. Pouches can appear anywhere between the throat and the stomach. They occur primarily in men and usually later in life.

Different names for the condition apply to different locations along the esophagus:

- Zenker's diverticula are pharyngeal pouches, or ones that occur in the upper neck area at the top of the esophagus.
- Traction diverticula are a type of mid-esophageal pouch.
- Epiphrenic diverticula occur at the bottom of the esophagus near where it enters the stomach.



A split x-ray image of the upper chest, neck, and esophagus (left), and chest and esophagus (right). *(Custom Medical Stock Photo, Inc.)*

WWW.BOOKBAZ.IR

Causes and symptoms

To propel food into the stomach (or out of it during **vomiting**) the esophagus generates internal pressure just like the bowel. Under certain circumstances, that pressure can herniate the esophageal lining through a weakness in the wall, creating a pouch (a balloon squeezed in the hand will herniate through the fingers in the same way). Pouches are more common in people who have motility disorders of the esophagus, swallowing that is not well coordinated and may be spastic. A **traction** diverticulum can develop from a scar that pulls the esophagus out of shape. Food and saliva can collect in all of these pouches.

Pouches in the neck usually cause **bad breath** (halitosis) and the regurgitation of swallowed food and saliva. Some patients with Zenker's diverticula can push on their neck and make old food appear in their mouths. Pouches near the stomach may cause swallowing problems, conditions known as *achalasia* or *dysphagia*. Mid-esophageal pouches usually cause no symptoms.

In the most serious cases, a person may be unable to swallow because the esophagus is obstructed, or the esphagus may rupture, spilling its contents into the chest or neck.

Diagnosis

Difficulty swallowing, bad breath, or food reappearing in the back of the mouth are among the signs physicians look for when diagnosing this condition. Sometimes the patient may also experience **pain** in the chest resembling a **heart attack**. A series of x rays taken while swallowing a contrast agent usually demonstrates the diverticulum clearly. An esophagoscopy may also be needed to gather more detail. Manometry, measuring pressures inside the esophagus using a balloon that is passed down it, may help determine the cause of the diverticula.

Treatment

Treatment for this condition is primarily aimed at alleviating symptoms. Physicians direct the patient to eat a bland diet, to chew his or her food thoroughly, and to drink water after eating to clean out the pouches. If the condition is severe, several types of surgery are available to remove the pouches and repair the defects. If a pouch is due to a stenosis (narrowing) in the esophagus it may be possible to relieve it by passing a dilator through it, a process called bougeinage.

KEY TERMS

Achalasia—Failure of the lower end of the esophagus (or another tubular valve) to open, resulting in obstruction, either partial or complete.

Contrast agent—A substance that produces shadows on an x ray so that hollow structures can be more easily seen.

Dysphagia—Difficult swallowing.

Esophagoscopy—Looking down the esophagus with a flexible viewing instrument.

Herniate—To protrude beyond usual limits.

Manometry—Pressure measurement.

Prognosis

The two complications that can render these nuisances dangerous, obstruction and rupture, are emergencies. Both require immediate medical attention. Diverticula will usually grow slowly over the years, gradually increasing the symptoms they cause.

Esophageal spasm

Definition

Esophageal spasm is uncoordinated or uncontrolled tightening of the muscles of the foodpipe.

Description

The esophagus is the muscular tube that actively transports food from the throat to the stomach by rhythmic contractions known as peristalsis. The actual anatomy and mechanism are complex. It involves three distinct and extremely powerful segments that function in a precise sequence, thus allowing a person to swallow even when upside-down. Diffuse esophageal spasm describes a condition

KEY TERMS

Contrast agent—A substance that produces shadows on x rays.

Manometry—Measurement of pressure.

Peristalsis—Slow, rhythmic contractions of the muscles in a tubular organ, such as the intestines, that propel the contents along.

where the entire esophagus is spastic—along its entire length, the muscular activity is increased and uncoordinated. The name "corkscrew esophagus" or "rosary bead" describes the appearance of this disorder as it may appear on x rays.

Causes and symptoms

The cause of esophageal spasm appears to be disruption of the complex system of nerves that coordinates the muscular activity. The result may be difficulty swallowing (dysphagia), the sensation of something trapped in the throat (globus), **heartburn**, spitting up undigested food, or **pain** that feels like a **heart attack** and can involve the entire chest, jaw, and arms.

Diagnosis

The physician will take the patient's history and perform a physical exam. Then may order an esophagram to investigate a swallowing problem. The patient will be told not to eat or drink before the exam. In the x-ray department, the patient is given a contrast agent to drink. During swallowing, x rays record the passage of the agent down the esophagus and into the stomach. Instead of a straight tube with well-coordinated waves of contraction, the resulting x rays would show a writhing organ resembling a giant corkscrew.

Another test that is used in many disorders of esophageal motility is manometry. Pressures inside the esophagus are measured every inch or so using a balloon device that is passed all the way down to the stomach. The result is a precise record of its activity that yields a specific diagnosis.

Treatment

Treatments may include changing the consistency of food, medications to control muscle contractions, balloon procedures through **endoscopy**, or perhaps more major surgery. Soft and liquid foods pass more easily than solid pieces. Medications of several types are helpful—nifedipine, hydralazine, isoproterenol, hyscyamine, sildenafil, and nitrates being the most successful. Low-dose antidepressants (especialloy tricyclics) can be helpful to some patients. Injection of botulinum toxin or mechanical dilatation of the esophagus can provide some relief to patients who have difficulty swallowing. For severe cases, relief is obtained two-thirds of the time by cutting the muscles along the entire length of the esophagus. This is a major surgical procedure, and reserved for those patients with **achalasia**, which prevents them from swallowing food and liquids.

Prognosis

This condition does not go away, nor is treatment entirely satisfactory. Patients need to be careful of what they eat and continue on medication if a beneficial one is found. Fortunately, the condition does not get progressively worse as time passes.

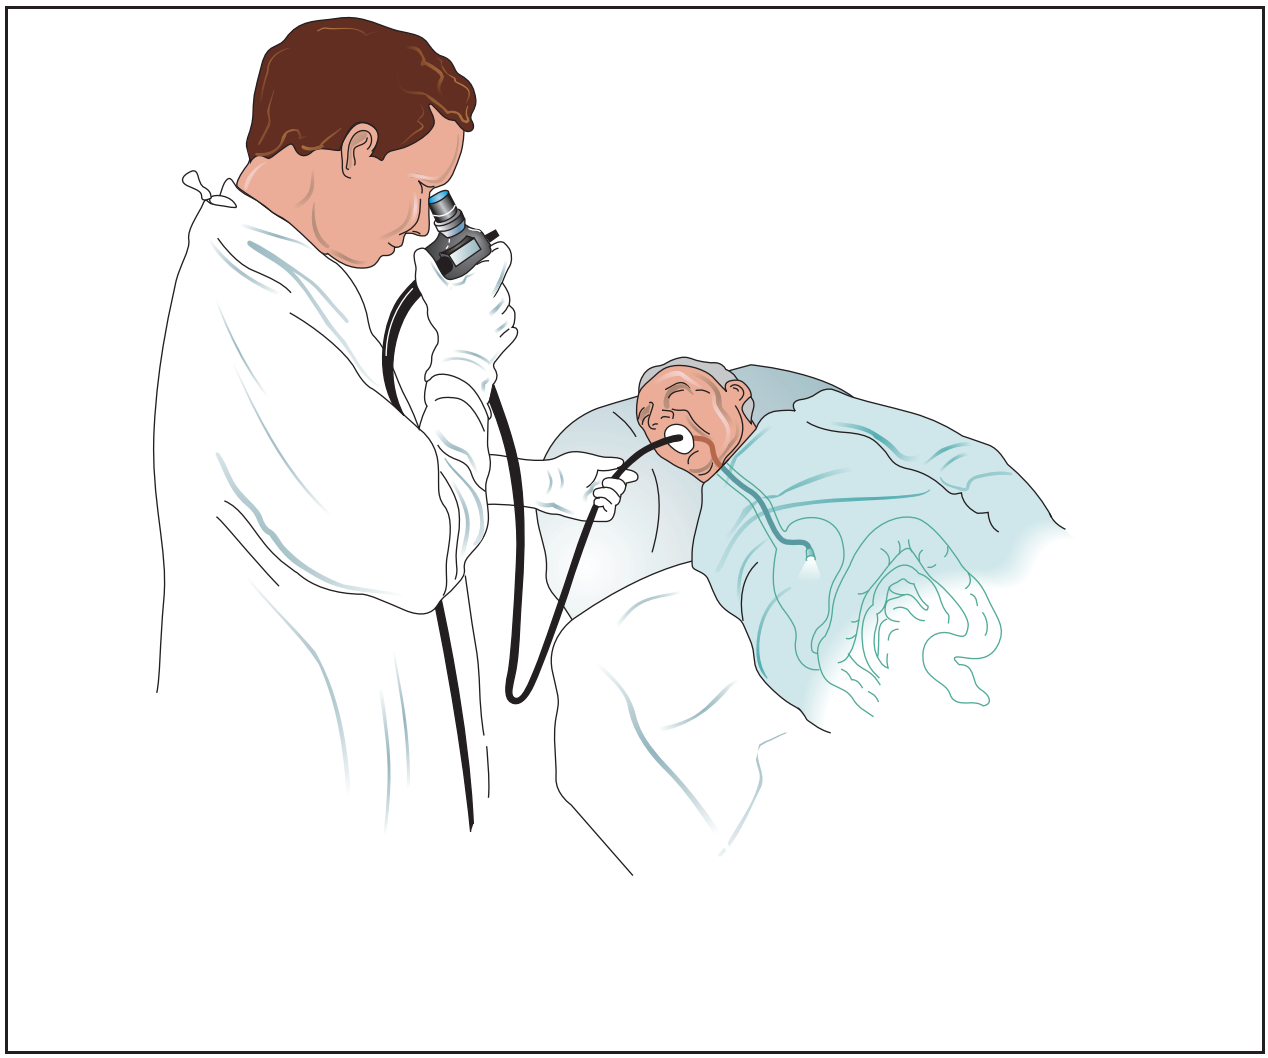
Esophageal ulcers *see* **Ulcers (digestive)**

Esophagogastroduodenoscopy

Definition

An endoscope as used in the field of gastroenterology (the medical study of the stomach and intestines) is a thin, flexible tube that uses a lens or miniature camera to view various areas of the gastrointestinal tract. When the procedure is limited to the examination of the inside of the gastrointestinal tract's upper portion, it is called upper **endoscopy** or esphagogastroduodenoscopy (EGD). With the endoscope,

WWW.BOOKBAZ.IR



Esophagogastroduodenoscopy (EGD) is performed to evaluate or treat symptoms relating to the upper gastrointestinal tract. By inserting an endoscope into the mouth and guiding it through the gastrointestinal tract, the esophagus, stomach, and duodenum can be examined and abnormalities treated. *(Illustration by Electronic Illustrators Group. © Cengage Learning®.)*

the esophagus (swallowing tube), stomach, and duodenum (first portion of the small intestine) can be easily examined, and abnormalities frequently treated. Patients are usually sedated during the exam.

Purpose

EGD is performed to evaluate or treat symptoms relating to the upper gastrointestinal tract, such as:

- upper abdominal or chest pain
- nausea or vomiting
- difficulty swallowing (dysphagia)
- bleeding from the upper intestinal tract
- anemia (low blood count). EGD can be used to treat certain conditions, such as an area of narrowing or bleeding in the upper gastrointestinal tract

Upper endoscopy is more accurate than x rays for detecting inflammation, **ulcers**, or tumors. It is used to diagnose early cancer and can frequently determine whether a growth is benign (not cancerous) or malignant (cancerous).

Biopsies (small tissue samples) of inflamed or "suspicious" areas can be obtained and examined by a pathologist. Cell scrapings can also be taken by the introduction of a small brush; this helps in the diagnosis of cancer or infections.

KEY TERMS

Pathologist—A doctor who specializes in the anatomic (structural) and chemical changes that occur with diseases. These doctors function in the laboratory, examining biopsy specimens, and regulating studies performed by the hospital laboratories (blood tests, urine tests, etc). Pathologists also perform autopsies.

When treating conditions in the upper gastrointestinal tract, small instruments are passed through the endoscope that can stretch narrowed areas (strictures), or remove swallowed objects (such as coins or pins). In addition, bleeding from ulcers or vessels can be treated by a number of endoscopic techniques.

Recent studies have shown the usefulness of endoscopic removal of early tumors of the esophagus or stomach. This is done either with injection of certain materials (like alcohol), or with the use of instruments (like lasers) that burn the tumor. Other techniques combining medications and lasers also show promise.

Precautions

Patients should inquire as to the doctor's expertise with these procedures, especially when therapy is the main goal. The doctor should be informed of any **allergies**, medication use, and medical problems.

Description

First, a "topical" (local) medication to numb the gag reflex is given either by spray or is gargled. Patients are usually sedated for the procedure (though not always) by injection of medications into a vein. The endoscopist then has the patient swallow the scope, which is passed through the upper gastrointestinal tract. The lens or camera at the end of the instrument allows the endoscopist to examine each portion of the upper gastrointestinal tract; photos can be taken for reference. Air is pumped in through the instrument to allow proper observation. Biopsies and other procedures can be performed without any significant discomfort.

Preparation

The upper intestinal tract must be empty for the procedure, so it is necessary not to eat or drink for at least 6–12 hours before the exam. Patients need to inquire about taking their medications before the procedure.

Aftercare

Someone should be available to take the person home after the procedure and stay with them for a while; patients will not be able to drive themselves due to **sedation**. **Pain** or any other unusual symptoms should be reported immediately.

It is important to recognize early signs of any possible complication. The doctor should be notified if the patient has **fever**, trouble swallowing, or increasing throat, chest, or abdominal pain.

Risks

EGD is safe and well tolerated; however, complications can occur as with any procedure. These are most often due to medications used during the procedure, or are related to endoscopic therapy. The overall complication rate of EGD is less than 2%, and many of these complications are minor (such as inflammation of the vein through which medication is given). Serious complications can and do occur, and almost half of them are related to the heart or lungs. Bleeding or perforations (holes in the gastrointestinal tract) are also reported, especially when tumors or narrowed areas are treated or biopsied. Infections have been rarely transmitted; improved cleaning techniques should be able to prevent them.

Evidence-based practice

Definition

Evidence-based practice is the process by which health care providers incorporate the best research or evidence into clinical practice, and combine that with clinical expertise and within the context of patient values.

Description

History

Evidence-based practice evolved out of an explosion of scientific literature and new techniques, medications, and technologies. Healthcare facilities were faced with rising medical costs and increased litigation, and consumers were calling for accountability in medicine. The medical profession began to seek new ways to ensure quality control of medical care. Basing medical procedures and practices on sound research became the means to find the best philosophical, legal, and practical fit for medical institutions and individual patients.

Historically, physicians and other healthcare providers were rooted in authority, basing their practice decisions on their knowledge of the mechanisms of disease and anatomy, their clinical observations, and traditional approaches. In the last half of the 20th century, this paradigm began to change as medical research increased and the resultant medical literature became more available to physicians, health care professionals, and patients.

Though **evidence-based medicine** had its beginnings in medical research in the mid-1800s, it was not until 1972, when Archie Cochrane's book, *Effectiveness & Efficiency* was published in the United Kingdom that the medical profession began to question how it delivered health care and started to take a methodical look at evidenced-based practice. Between 1985 and 1990, an international collaboration undertook systematic reviews of literature in the field of **pregnancy**, **childbirth**, and neonatal medicine. In 1992, the Cochrane Centre (now the UK Cochrane Centre) was begun to prepare systematic reviews of all areas of health care and to eventually establish a database.

In the United States, the Agency for Health Care Policy and Research was originated in 1989 as part of the Department of Health and Human Services. It was reorganized in 1999 as the Agency for Healthcare Research and Quality. It funds grants to universities and other institutions to conduct research that will help healthcare providers make informed decisions on quality outcomes. This was the basis for modern evidence-based medicine in America.

Evidence-based practice developed by incorporating scientific research with clinical experience and patient preferences. This process looks not just at research findings about new medications, technologies, and procedures, but also at how that information applies to a specific clinical setting and to an individual patient. In order to do that, the clinical experience of healthcare professionals and a patient's values and needs had to fit into the healthcare outcome.

The process

Since organizations for formal systematic reviews of scientific literature have been established, various groups of healthcare professionals have drafted their own versions of evidence-based practice guidelines. Many professional organizations, such as those that represent oncology nurses, surgical nurses, and pediatric health professionals have created resources to aid their members in this process.

In general, six tasks are involved in evidence-based practice. They are:

1. identifying a problem
2. researching the literature
3. critiquing the evidence
4. formulating recommendations
5. implementing practice changes
6. evaluation

1. IDENTIFYING A PROBLEM. Needs arise in clinical practice regularly, especially when a knowledge gap surrounds a new procedure or practice, or when a question arises concerning the best approach to use in a specific situation. Knowledge gaps may be related to diagnosis, prognosis, therapy, prevention, or professional education. The latter encompasses the best teaching strategies for educating patients, family members, or other healthcare professionals about a new procedure, therapy, or medication.

Once the need is identified, the team must formulate a question that is answerable through research of the scientific literature, and that has a measurable outcome. This will focus the process. The team also drafts a timetable for the complete evidence-based process to take place.

2. RESEARCHING THE LITERATURE. The team begins searching the scientific literature, which can be time-consuming, but is essential to the success of the clinical process. Generally, the literature includes articles in

peer-reviewed medical journals, such as the *Journal of the American Medical Association (JAMA)*, in which academic and research-oriented doctors publish their findings. In other cases, information may come from presentations made at academic or practitioner conferences. Finding resources can be problematic, however, especially if the research question is very narrow or if it involves a new technology that has had little written about it.

3. CRITIQUING THE EVIDENCE. The results of a literature search must not only fit the clinical problem, the clinical setting, and the specific patient population under consideration, but also be scientifically sound. Results should be scrutinized, and the demographics, methods, and validity of the study should also be evaluated. For instance, the team should consider whether the patients in the study were randomly assigned to experimental and control groups, and if other studies have replicated the results.

The healthcare team should evaluate the recommendations of the study to determine if they are sound, practical, and clinically relevant to the research question.

4. FORMULATING RECOMMENDATIONS. The entire evidence-based practice team comes together to synthesize all of the recommendations found in the strongest scientific studies. This requires further evaluation so that the team can determine the specific advantages of the procedures. At this point, practice relevance is the most important factor. Team members will need to answer several questions:

- Does the evidence support a change in clinical practice?
- Can the recommendations in the evidence be applied to the current practice setting and patient population?
- Are resources available for this practice change?
- Will administrative support be available for this new intervention?

5. IMPLEMENTING PRACTICE CHANGES. Though the evidence-based practice team may have made a clear recommendation, the incorporation of changes may not be automatic, nor should they be. Implementing a clinical change involves planning and preparation, not just learning how to perform a new procedure. Often, it will involve preparing staff members for these changes, which includes informing them about the philosophy of evidence-based practice and how it can help their professional lives.

The following step identifies expected outcomes from the clinical change that are both measurable and relevant to the institution where the change will occur. Baseline data should be collected in order to compare the success or failure of the change. Expected costs should be determined and resources tapped for the change. In addition, barriers to the clinical change should be identified. These barriers can involve administrative support, staff acceptance and compliance, competency of the staff, costs, the cultural climate of the institution, and the timing of the change. Some barriers, such as a major remodeling or personnel change, may be insurmountable.

Next, a trial or pilot is initiated. This will assess the practicality of the clinical change in the appropriate setting and patient population. If the change is deemed feasible, the staff is educated about the change, including its rationale and the evidence behind it.

The practice change is then reviewed, and may result in a decision to broaden its use into the clinical setting.

6. EVALUATION. Further evaluation will determine the effectiveness of the change in clinical practice, especially in comparison with baseline data collected before the change went into effect. Evaluations are conducted over the short term, which may be only a few weeks or months following the change; or over a longer term, which may be a year or more. Evaluations typically include specific monitoring criteria that observe whether the new practice is being done correctly; its effects on staff morale and effectiveness; its effects on patient outcomes; and the costs surrounding the practice change.

Risks

Evidence-based practice is designed to lower healthcare risks and improve patient outcomes. It helps ensure that consumers receive the best possible care, based on the most up-to-date scientific information.

The patient is at the center of evidence-based practice: The needs generated by a patient's medical situation drives the question that the health care staff addresses and researches. If a consumer is concerned about whether a diagnosis, treatment, or procedure is supported by current medical research, he or she should not be afraid to ask the healthcare provider recommending the procedure.

Evidence-based practice creates a better climate in which healthcare professionals can bring higher quality of care. Old, outdated methods and procedures can be eliminated and newer, more efficient ones can replace them. Though evidence-based practice deals with one problem or question at a time, it has the potential to streamline and modernize patient care.

WWW.BOOKBAZ.IR

KEY TERMS

Cultural climate—The political and social environment of an institution or a society.

Validity—Measurement validity refers to whether a test is measuring what it claims to.

This slow, constant work to bring patient-care in line with the most up-to-date thinking helps patients during all aspects of health care, including screenings, diagnosis, and treatment.

Evidence-based practice results in constantly evolving standards of care, some of which may cause debate within the medical community. While the process is ultimately meant to improve care, this can be confusing to consumers. For example, in 2009, the U.S. Preventive Services Task Force laid out new guidelines for mammograms for women, recommending that screening begin at age 50 and be done every two years. This contrasted with the previous recommendation of annual mammograms beginning at age 40. The new guidelines led to strenuous debate, some of which has continued into 2014, as various medical and other groups weigh in on the changes, and researchers publish many new articles in support of or in opposition to the new guidelines. This type of ongoing, heated debate can make it difficult for consumers to know what screening schedule is appropriate, but by consulting with a physician who is up-to-date on the relevant literature, consumers can sort through the information and determine what strategy is best for them and for their health.

Evoked potential studies

Definition

Evoked potential studies are a group of tests of the nervous system that measure electrical signals along the nerve pathways.

Purpose

Nerves convey information to the body by sending electrical signals down the length of the nerve.

These signals can be recorded by wires placed over the nerves on the surface of the skin, in a procedure called an evoked potential (EP) study. The person conducting the test evokes the patient's neural activity by visual or auditory stimulation or using a mild electrical shock. This causes changes in the electrical potential in the nerves. Analysis of the signals can provide information about the condition of nerve pathways, especially those in the brain and spinal cord. They can indicate the presence of disease or degeneration, and can help determine the location of nerve lesions.

There are three major types of EP studies used regularly:

- Visual evoked potentials are used to diagnose visual losses due to optic nerve damage, especially from multiple sclerosis. They are also useful to diagnose "hysterical blindness," in which loss of vision is not due to any nerve damage.
- Auditory evoked potentials are used to diagnose hearing losses. They can distinguish damage to the acoustic nerve (which carries signals from the ear to the brain stem) from damage to the auditory pathways within the brainstem. Most auditory EPs record activity from the brainstem, and are called "brainstem auditory evoked potentials." Disorders diagnosed with auditory EPs include acoustic neuroma (tumors of the inner ear) and multiple sclerosis (chronic disease in which nerves lose patches of their outer covering). They may also be used to assess high frequency hearing ability, to determine brain death, and to monitor brainstem function during surgery.
- Somatosensory evoked potentials record transmission of nerve impulses from the limbs to the brain, and can be used to diagnose nerve damage or degeneration within the spinal cord or nerve roots from multiple sclerosis, trauma, or other degenerative disease. Somatosensory EPs can be used to distinguish central versus peripheral nerve disease, when combined with results from a nerve conduction velocity test, which measures nerve function in the extremities.

Precautions

Evoked potential studies are painless, noninvasive, and without any significant risk. Somatosensory EP tests involve very mild electric shocks, usually felt as a tingling.

Description

The person performing the test locates and marks specific spots on the patient's head for placement of electrodes. These spots are cleaned, and an adhesive conducting paste is applied. Cup electrodes are attached. For somatosensory EP, spots on the arm or leg are also marked and cleaned; electrodes may be taped in place. The patient sits or reclines in a chair throughout the tests.

For a visual EP, the patient focuses on a TV screen that displays a checkerboard pattern. The eye not being tested is covered with a patch. For children or others whose attention may wander, goggles are used that show the pattern to one eye at a time. Each eye is usually tested twice, and the entire procedure takes approximately 30–45 minutes.

For auditory EP, headphones are used to deliver a series of clicks to one ear at a time. A masking or static sound is played into the other ear. Each ear is usually tested twice, and the entire procedure takes approximately 30–45 minutes.

For somatosensory EP, mild electrical shocks are delivered to the arm or leg. This may cause some twitching and tingling. The stimulus lasts for about two minutes at a time, and the entire procedure takes approximately 30 minutes.

After the tests, the electrodes are removed with acetone and the scalp is cleaned.

Preparation

Hair must be clean, dry, and free of any braids, pins, or jewelry. The patient should shampoo before the test, and must not use any hair spray, gel, or other hair care products after shampooing. Clothing should be loose and comfortable. The patient may eat and take some medications as usual before the test, although sedative medications should be avoided on the day of the test, if possible. It is best to check with the physician supervising the test for specific instructions.

Aftercare

This test is painless and has no residual effects. The patient may return to work or other activities immediately afterward.

Results

EP test results are displayed as jagged electrical tracings (wave forms), which have characteristic shapes, heights, and lengths, indicating the speed and intensity of signal transmission. Results are read by someone trained in evoked potential studies.

WWW.BOOKBAZ.IR

KEY TERMS

Nerve conduction velocity test—A test of the speed of conduction of nerves, performed on the nerves in the arm and leg.

Abnormal results

Changes in the electrical tracings may indicate damage to or degeneration of nerve pathways to the brain from the eyes, ears, or limbs. Absence of any activity may mean complete loss of nerve function in that pathway. Other changes may provide evidence of the type and location of nerve damage.

Exercise

Definition

Exercise can be defined as physical activity that involves planned, structured, and repetitive bodily movements for the purpose of maintaining or improving physical fitness and overall health. Exercise includes cardiovascular training, muscle-strength training, and stretching activities for flexibility and to prevent injury. Typical exercise activities include walking, running, cycling, swimming, weight training, aerobics, and individual and team sports.

Purpose

Regular exercise is important for the physical, mental, and emotional health of people of all ages—from young children to the elderly. Exercise promotes:

- weight maintenance or weight loss
- cardiovascular efficiency
- musculoskeletal strength and flexibility
- improved functioning of the metabolic, endocrine, and immune systems
- bone density
- lower cholesterol levels
- recovery from illness, injury, or surgery
- mental and emotional well-being

The beneficial effects of exercise diminish within two weeks of substantially reducing physical activity. Physical fitness is lost completely if exercise is not resumed within two to eight months.

Demographics

The National Institutes of Health (NIH) has identified inactivity as a major **public health** problem in the United States, and most North American adults would benefit from increasing their level of physical activity. More than 60% of American adults do not get enough physical activity to provide health benefits and more than 25% are inactive during their leisure time. Lack of exercise is a major contributor to the current epidemic of **obesity**, since people burn fewer calories than they take in, resulting in weight gain. Sedentary lifestyles and unhealthy eating patterns are responsible for at least 300,000 deaths from chronic disease each year in the United States. Likewise a recent survey in the United Kingdom found that only one-third of adults meet recommended goals for physical activity.

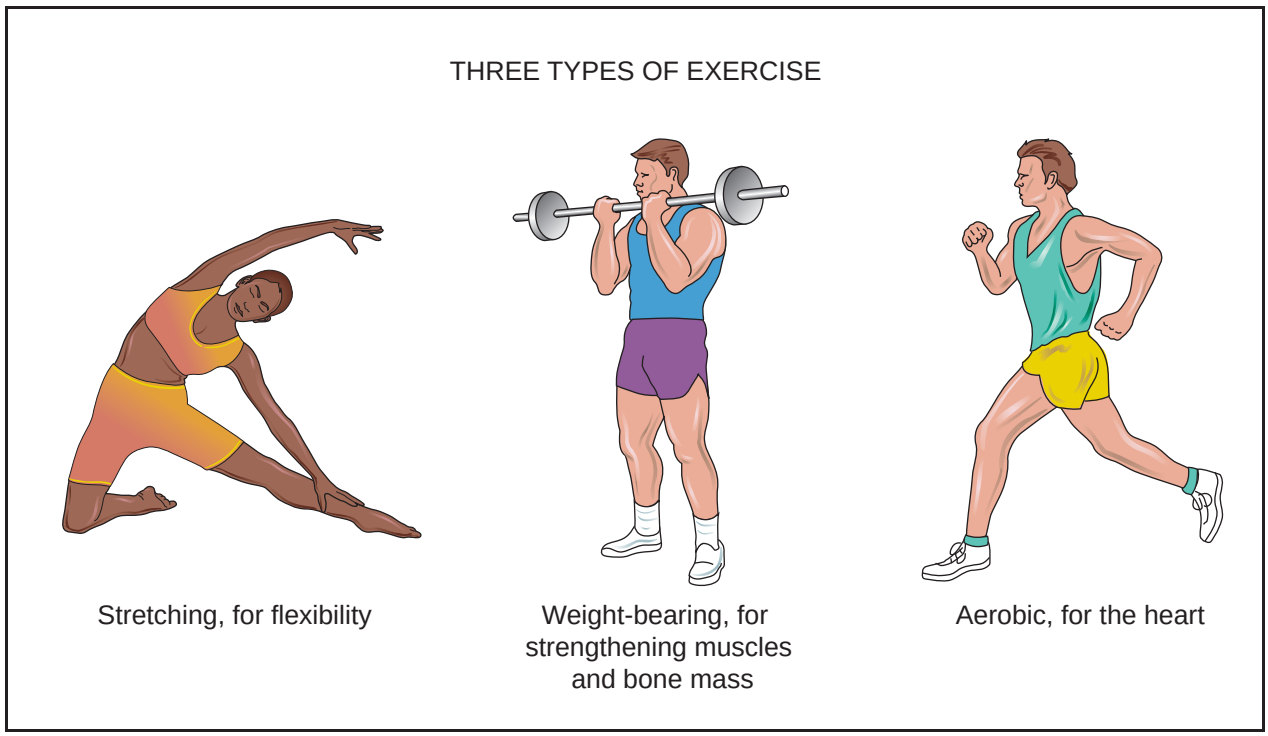
Insufficient exercise is more prevalent among women than men and among those with lower levels of economic stability and educational achievement. However, the number of adult Americans who are exercising regularly is on the increase. According the Centers for Disease Control and Prevention (CDC), between 2001 and 2005 the number of women exercising at least 30 minutes per day increased by 8.6% and the number of men increased by 3.5%.

Geriatric

Exercise generally decreases with age. It is estimated that two-thirds of Americans over age 65 have at least one chronic condition, with 36 million having some form of arthritis. Lack of exercise is a significant contributor to conditions such as **osteoarthritis**, lower back **pain**, and **osteoporosis**. More than 300,000 total joint replacements are performed each year due to osteoarthritis.

Description

Exercise programs should include three types of exercise: strengthening, including weight or resistance training, stretching and flexibility exercises, and



Exercise is utilized to improve health, maintain fitness, and is important as a means of physical rehabilitation. *(Illustration by Electronic Illustrators Group. © Cengage Learning®.)*

cardiovascular exercise. Recent studies have indicated that muscle strength and aerobic fitness make independent contributions to health and that more muscle strength correlates with lower death rates, regardless of aerobic fitness. The American College of Sports Medicine recommends two strength-training workouts per week, each consisting of about ten repetitions of ten exercises for strengthening all of the major muscle groups. **Yoga** is often recommended for stretching, bending, and improving overall flexibility.

Chosen exercises should be interesting and appealing: studies have found that people are more likely to stick with an exercise program when they enjoy the activity, whether as an individual, with a partner, or with a group or team. Convenience is also an important consideration. Exercise can take place at home, outdoors, at a health club or fitness center, school, church, or community center. Taking a class, working out with a friend, competing, or setting personal goals can help maintain motivation. Walking for exercise can be combined with various enjoyable activities, such as bird watching, museum visits, window shopping, or exercising the dog. Group exercises and team sports are good ways to socialize. Varying exercise routines every few weeks can benefit different muscle groups and help prevent boredom. In addition, since the human body adjusts rapidly to most exercises, continuing the same routine for too long can result in decreased benefits.

The most efficient cardiovascular exercises for improving physical fitness include:

- brisk walking (3–4 mph), whether outside, in a mall, or on a treadmill
- jogging
- running
- bicycling, either outside or on a stationary bike
- stair climbing
- elliptical cross-training on exercise machines
- aerobics
- swimming
- water exercise or aerobics
- rowing
- cross-country (Nordic) skiing
- jumping rope—a particularly good exercise for children

Other exercises that provide cardiovascular conditioning—but are less endurance-promoting because they usually require frequent starting and stopping—include:

- dancing

WWW.BOOKBAZ.IR

- basketball
- soccer
- softball
- badminton
- racquetball
- squash
- tennis
- table tennis
- volleyball
- skating
- golfing, if walking and carrying clubs

Teenagers can get cardiovascular exercise through school sports including:

- baseball
- cross country
- track and field
- cheerleading
- drill team
- field hockey
- football
- lacrosse
- wrestling

People who are generally sedentary can still get exercise through their occupation, housework, home repair, gardening, using stairs instead of an elevator, and various recreational pursuits. People with health problems can find exercises that accommodate their injuries or disorders. The American Council on Exercise suggests specific exercises for the elderly and for adults with problems such as **asthma**, chronic pain, bad knees, shoulder injuries, arthritis, and flat feet.

Regularity and intensity are key elements of exercise. It has generally been recommended that all adults get at least 30 minutes of moderate-intensity exercise on most days of the week. The most recent consensus is to aim for 150 minutes per week, regardless of how it is divided up. The latest evidence suggests that three 10-minute bouts of exercise are as beneficial as one 30-minute workout. Improving cardiovascular endurance requires at least 20–60 minutes of cardiovascular exercise three to five days per week. The U.S. Department of Health and Human Services recommends at least 60 minutes of physical activity for children and teens on most or all days of the week.

Defining "moderate intensity" can be tricky. Until recently exercise intensity was generally gauged by increased heart rate. However, intensity is more accurately measured by metabolic rate, as represented by units of metabolic equivalents or METS. METS is an individual's metabolic rate during exercise divided by the metabolic rate when sitting still. The latter is defined as 1 kilocalorie per kilogram (kg) of body weight per hour or an oxygen uptake of 3.5 milliliters per kg per minute. Moderate activity is defined as 3–6 METS. Although a precise measurement requires determining oxygen intake in a laboratory, charts of average METS for various activities are available. Examples of METS include:

- walking, 2–8
- running, 8–18
- bicycling, 4–16
- stationary bicycling, 3–12.5
- general health-club exercise, 5.5
- calisthenics, 3–8
- weight lifting, 3–6
- swimming, 6–11
- cross-country skiing, 7–16.5
- downhill skiing, 5–8
- volleyball, 3–8
- dancing, 3–10
- basketball, 4.5–8
- tennis, 5–8
- tai chi, 4
- stretching, hatha yoga, 2.5
- household tasks, 2–9
- mowing with a hand mower, 6

Exercise geared to a target heart rate is typically about 70% of the maximum heart rate for one's age. Heart rate is calculated by counting the pulse, usually about halfway through a 20–30-minute workout. Fingers are placed firmly but lightly over the inside of the wrist or on the neck just below the angle of the jaw; however too much pressure on the neck can slow down the heart rate. The palm also can be placed over the heart to count the number of beats. A zero is added to a six-second count or a 10-second count is multiplied by six to obtain the beats per minute (bpm). Maximum bpm is calculated by subtracting one's age from 220. For example:

- Target heart rate during cardiovascular exercise for a healthy 50-year-old might be 170 multiplied by 70% or 119 bpm.
- A particularly fit 50-year-old might have a target heart rate of 80% of maximum or 136 bpm.
- A 50-year-old with a medical condition may have a target exercising heart rate of only 50% or 85 bpm. A bpm above the target rate indicates a need to slow down, whereas a bpm below the target indicates a need to speed up the pace of exercise.

There are other methods for measuring the intensity of cardiovascular exercise:

- Classes and DVDs usually include a timed heart-rate check and a chart of target rates by age.
- Electronic exercise pulse monitors are available.
- A simple "talk test" is based on speaking a complete sentence: the pace of exercise is too high if the sentence cannot be completed and too low if it is overly easy to speak the sentence.
- Cardiovascular exercise usually involves sweating; therefore, people who no longer sweat during their exercise routine may need to increase the intensity, duration, or frequency of their workouts.

Improved fitness in response to exercise appears to be genetically determined and to run in families. Some previously sedentary people show less improvement in fitness than would be expected following weeks of a vigorous exercise program and about 10% show no improvement at all. Even those who show no improvement in fitness measures still respond to exercise with lowered blood pressure and **cholesterol**, improved insulin levels, and less abdominal fat.

Origins

Throughout most of human history, most people had plenty of exercise. Then, early in the twentieth century, the rate of heart attacks in Western countries began to increase dramatically. The first indication that this might be due to lack of exercise came in a landmark 1953 study of London bus conductors: conductors, who spent their days collecting fares from seated passengers and walking up and down the stairs of double-decker buses, had half the number of heart attacks as seated bus drivers. Since then countless studies have confirmed the positive effects of exercise, not just on the heart and circulatory system, but on virtually every system of the body.

Benefits

Exercise promotes:

- cardiovascular fitness, including improved heart function and increased heart, lung, and muscle endurance
- muscle strength and mass
- flexibility
- weight loss
- lowered blood pressure
- bone density and strength, which reduces the risk of fractures and osteoporosis
- mental health and psychological and emotional well-being from the release of brain hormones called endorphins

Additional benefits of cardiovascular exercise include:

- improved immune system function
- improved utilization and control of blood sugar
- decreased cholesterol and triglycerides
- decreased abdominal fat
- increased energy levels
- less fatigue
- improved appetite
- improved sleep
- reduced stress
- pain reduction

Regular exercise lowers the risk of a **heart attack** by 50–80%. Exercise also has been shown to reduce the risk of:

- stroke
- cancer
- diabetes
- liver and kidney disease
- osteoporosis
- depression
- dementia

Even those who are overweight or obese can become aerobically fit with exercise. Studies have found that the risk of dying is more closely related to fitness than to weight. In fact people who are fit but obese have a lower risk of dying than people who are unfit but of normal weight.

More than 30 million Americans undergo surgery each year. Each patient's surgical risk, complications, and outcome depend, at least in part, on their physical fitness: how well their cardiovascular and pulmonary systems withstand the **stress** of **anesthesia**; how quickly their bones and muscles recover after surgical procedures; and how well their metabolic and immune systems respond to surgery and the risk of infection.

Precautions

- Everyone should have a physical examination before embarking on an exercise program for the first time or after a long period of inactivity.
- Exercise intensity and duration should be increased gradually.

WWW.BOOKBAZ.IR

KEY TERMS

Aerobic exercise—Any exercise that increases the body's oxygen consumption and improves the functioning of the cardiovascular and respiratory systems.

Cholesterol—A fat-soluble steroid alcohol (sterol) found in animal fats and oils and produced in the body from saturated fats. High cholesterol levels contribute to the development of cardiovascular disease.

Endorphins—A class of peptides in the brain that are produced during exercise and bind to opiate receptors, resulting in pleasant feelings and pain relief.

Metabolic equivalent of task; MET—The energy cost of a physical activity, measured as a multiple of the resting metabolic rate, which is defined as 3.5 milliliters of oxygen consumed per kilogram (kg) of body weight per minute, equivalent to 1 kilocalorie per kg per hour.

Obesity—Excessive weight due to accumulation of fat, usually defined as a body mass index (BMI) of 30 or above or body weight greater than 30% above normal on standard height-weight tables.

Physical activity—Any activity that involves moving the body and burning calories.

Physical fitness—A combination of muscle strength, cardiovascular health, and flexibility that is usually attributed to regular exercise and good nutrition.

Sedentary—Inactivity and lack of exercise; a lifestyle that is a major risk factor for becoming overweight or obese and developing chronic diseases.

Stress test—An electrocardiogram recorded before, during, and after a period of increasingly strenuous cardiovascular exercise, usually on a treadmill or stationary bicycle.

Target heart rate—The heart rate, in beats per minute (bpm), that should be maintained during cardiovascular exercise by an individual of a given age.

Triglycerides—Neutral fats; lipids formed from glycerol and fatty acids that circulate in the blood as lipoprotein. Elevated triglyceride levels contribute to the development of cardiovascular disease.

- People who are very weak may need to build strength before they can participate in cardiovascular exercise.
- Warming up before and stretching after exercise are very important.
- People should pace themselves and check their heart rate or otherwise judge their level of exertion.
- If exercising becomes "very hard" or worse, it is important to slow the pace.
- Although some discomfort, such as aches or stiffness, are to be expected during the first few days of a new exercise, if pain is intrusive it is important to stop the activity or get instruction on technique.
- Strenuous cardiovascular exercise should never be halted abruptly without a cool-down, since blood that has concentrated in the working muscles can pool and cause dizziness or lightheadedness.
- Cardiovascular exercise requires a healthy diet with plenty of vegetables.
- It is best to wait up to two hours after a full meal before exercising and about an hour after exercising before having a meal, although a small healthy snack before exercising can boost energy levels.
- It is important to drink enough fluid to replace water that is lost as sweat; coffee, tea, colas, chocolate, or alcohol can cause the body to lose fluid.
- Simple home exercises, such as a balance board, can reduce the risk of recurrent sprained ankles.
- Taking a few days off from cardiovascular exercise every month can help rejuvenate the body.

Geriatric

Both maximum heart rate and cardiac output are lower in older adults, in part due to a decrease in the beta-adrenergic response. Older adults should have a **stress test** before embarking on a cardiovascular exercise program. A good result on a stress test is a bpm that is 80% of the age-adjusted maximum, with 90% considered excellent.

Other conditions

Various medical conditions can affect exercise. For example people with back problems should avoid exercises that require twisting or vigorous forward movements, such as aerobic dancing or rowing. People with spinal disk disease should avoid high-impact activities.

Preparation

Exercise should begin with a light or very light warm-up of five to ten minutes that may include gentle stretching to loosen muscles and joints and help

prevent injury. The warm-up may involve slowly beginning the conditioning activity—warming up for a brisk walk or jog by walking slowly or strolling, or warming up to ride a stationary bike by pedaling slowly with no resistance. Warming up increases blood flow to the muscles, increases muscle temperature, and prepares them to work harder.

Aftercare

Cardiovascular exercise should be followed by a light or very light five- or ten-minute cool-down to allow the heart and circulation to gradually return to a resting state. The cool-down can include the same activity as the conditioning phase at a slower pace—slower walking or pedaling with reduced resistance on a stationary bike.

Most doctors encourage patients to become active as soon as possible following surgery. Aftercare is individualized and there may be limitations on physical activity; however, the goal is to return the patient to normal daily activities and exercise routines. Patients should ask for explicit guidelines concerning exercise.

Risks

Exercise poses a risk of injury, particularly if exercises are inappropriate or improperly performed. Too much exercise can be as harmful as too little; overuse of certain muscles and joints can lead to problems such as **tennis elbow** or **shin splints**. High-intensity exercises, such as high-impact aerobics and jogging, are not recommended as frequently as in the past. Running, in particular, is hard on the knees and ankle joints, and there is a risk of sprained ankles and injuries from falls. About one half of all regular runners and players of team sports develop some type of musculoskeletal injury each year.

Inadequate rest increases the risk of **stroke** and circulatory problems. Injury or illness from overtraining is sometimes indicated by a high resting heart rate, sleeping difficulties, or exhaustion. The risk of a heart attack can rise as much as 100-fold for a completely unfit individual who undertakes vigorous exercise such as jogging or shoveling snow. In contrast, a person who runs five times per week merely doubles their risk of heart attack during vigorous exercise. The risk of heart attack subsides about one-half hour after exercising and pales in comparison to the lifetime benefits of regular exercise.

Pregnant or breastfeeding

Some types of exercise are inappropriate for pregnant women. Pregnant women are generally advised not to exercise for two consecutive days.

Exophthalmos

Definition

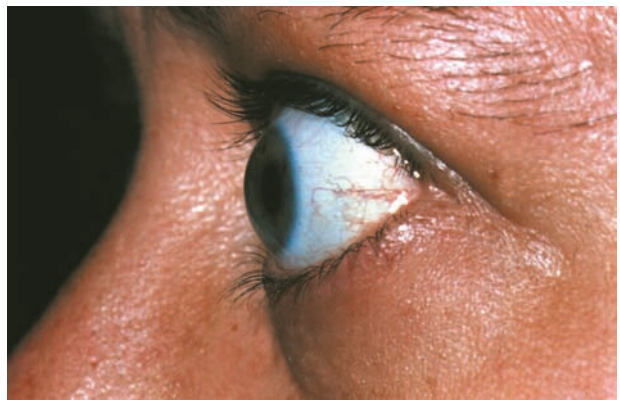
When there is an increase in the volume of the tissue behind the eyes, the eyes will appear to bulge out of the face. The terms exophthalmos and proptosis apply. Proptosis can refer to any organ that is displaced forward, while exophthalmos refers just to the eyes.

Description

The eye socket (orbit) is made of bone and therefore will not yield to increased pressure within it. Only forward displacement of the eyeball (globe) will allow more room if tissue behind the eye is increasing.

Causes and symptoms

The most common cause of exophthalmos is Graves' disease, overactivity of the thyroid gland. The contents of the orbits swell due to inflammation, forcing the eyes forward. The inflammation affects primarily the muscles. This combination of muscle impairment and forward displacement reduces eye movement, causing double vision and crossed eyes (**strabismus**). The optic nerves can also be affected, reducing vision, and the clear membrane (conjunctiva) covering the white part of the eyes and lining the inside of the eyelids can swell. Finally, the eyes may protrude so far that the eyelids cannot close over them, leading to corneal damage.



A side view of the bulging eye (exophthalmos) of a person with thytoxicosis. Exophthalmos is caused by swelling of the soft tissue in the eye socket, which forces the eyeball to be pushed forward and the eyelids stretched apart. *(Dr. P. Marazzi/Photo Researchers, Inc.)*

Exophthalmos from Graves' disease is bilateral (occurring on both sides), but not necessarily symmetrical. In contrast, exophthalmos from orbital tumors or a blood clot in the brain happens on only one side.

Diagnosis

Exophthalmos is obvious when it is advanced enough to cause complications. When there is doubt in the early stages, a mechanical device called an exophthalmometer can measure the protrusion. **Computed tomography scans** (CT scans) are of great value in examining the bony components of the orbit. **Magnetic resonance imaging** (MRI) scanning is equally valuable for displaying the contents of the orbit, because it "sees through" the bone.

Treatment

If a tumor is growing behind the eye, it needs to be removed. If Graves' disease is the cause, it may subside with treatment of the overactive thyroid, but this is not guaranteed. Local care to the front of the eye to keep it moist is necessary if the eyelid cannot close.

Prognosis

Exophthalmos can be progressive. Its progress must be carefully followed, treating complications as they occur.

KEY TERMS

Conjunctivae—The clear membranes that line the inside of the eyelids and cover the white part (sclera) of the eyeballs.

Cornea—The clear, dome-shaped part of the front of the eye, through which light first enters the eye. It is located in front of the colored part of the eye (iris).

Inflammation—The body's reaction to invasion by foreign matter, particularly infection. The result is swelling and redness from an increase in water and blood, and pain from the chemical activity of the reaction.

Strabismus—Any deviation of the eyes from a common direction. Commonly called a turned eye.

Thyroid—A gland in the neck overlying the windpipe that regulates the speed of metabolic processes by producing a hormone, thyroxin.

Prevention

Vision can usually be preserved with attentive treatment. There is currently no way to prevent any of the underlying conditions that lead to exophthalmos.

J. Ricker Polsdorfer, MD

Expectorants

Definition

Expectorants are drugs that loosen and clear mucus and phlegm from the respiratory tract.

Purpose

Guaifenesin is a common ingredient in **cough** medicines. It is classified as an expectorant, a medicine that helps clear mucus and other secretions from the respiratory tract. Some debate exists about how effectively guaifenesin does this. In addition, some cough medicines contain other ingredients that may cancel out guaifenesin's effects. **Cough suppressants** such as codeine, for example, work against guaifenesin because they discourage coughing up the secretions that the expectorant loosens.

There are other ways to loosen and clear the respiratory secretions associated with colds. These include using a humidifier and drinking six to eight glasses of water a day.

Description

Guaifenesin is an ingredient in many cough medicines, such as the brand names Anti-Tuss, Dristan Cold & Cough, Guaifed, GuaiCough, and some Robitussin products. Some products that contain guaifenesin are available only with a physician's prescription; others can be bought without a prescription. They come in several forms, including capsules, tablets, and liquids.

Recommended dosage

Adults and children 12 and over

200–400 mg every four hours. No more than 2,400 mg in 24 hours.

Children 6–11

100–200 mg every four hours. No more than 1,200 mg in 24 hours.

Children 2–5

50–100 mg every four hours. No more than 600 mg in 24 hours.

Children under two

Not recommended.

Precautions

Do not take more than the recommended daily dosage of guaifenesin.

Guaifenesin is not meant to be used for coughs associated with **asthma**, **emphysema**, chronic **bronchitis**, or **smoking**. It also should not be used for coughs that are producing a large amount of mucus.

A lingering cough could be a sign of a serious medical condition. Coughs that last more than seven days or are associated with **fever**, rash, **sore throat**, or lasting **headache** should be evaluated by a physician.

WWW.BOOKBAZ.IR

KEY TERMS

Asthma—A disease in which the air passages of the lungs become inflamed and narrowed.

Bronchitis—Inflammation of the air passages of the lungs.

Chronic—A word used to describe a long-lasting condition. Chronic conditions often develop gradually and involve slow changes.

Cough suppressant—Medicine that stops or prevents coughing.

Emphysema—An irreversible lung disease in which breathing becomes increasingly difficult.

Mucus—Thick fluid produced by the moist membranes that line many body cavities and structures.

Phlegm—Thick mucus produced in the air passages.

Respiratory tract—The air passages from the nose into the lungs.

Secretion—A substance, such as saliva or mucus, that is produced and given off by a cell or a gland.

Some studies suggest that guaifenesin causes **birth defects**. Women who are pregnant or plan to become pregnant should check with their physicians before using any products that contain guaifenesin. Whether guaifenesin passes into breast milk is not known, but no ill effects have been reported in nursing babies whose mothers used guaifenesin.

Side effects

Side effects are rare, but may include **vomiting**, **diarrhea**, stomach upset, headache, skin rash, and **hives**.

Interactions

Guaifenesin is not known to interact with any foods or other drugs. However, cough medicines that contain guaifenesin may contain other ingredients that do interact with foods or drugs. Check with a physician or pharmacist for details about specific products.

External sphincter electromyography

Definition

External sphincter **electromyography** helps physicians determine how well the external urinary sphincter muscle is working by measuring the electrical activity in it during contraction and relaxation.

Purpose

The external sphincter muscle is the ring-like muscle that controls urine release from the bladder. When a patient cannot voluntarily control urination (incontinence), a physician may order this test to determine if the problem is caused by the failure of this muscle. The voluntary contraction or release of a muscle such as the external sphincter involves a complex process in which the nerves controlling the muscle signal it to move through the release and uptake of chemicals called neurotransmitters and the generation of electrical impulses. This test records the electrical impulses given off when the muscle contracts or relaxes and allows the physician to determine if the muscle is working properly, if it has been damaged by disease, or some other condition.

Precautions

Patients who are taking **muscle relaxants** or drugs that act like or have an effect on the neurotransmitter acetylcholine (cholinergic or anti-cholinergic drugs) should tell the doctor since they will change the test results. The results will also be altered if the patient moves during the test or if the electrodes are improperly placed.

Description

The patient puts on a surgical gown and lies down on the examining table. The procedure, which takes between 30–60 minutes, may be conducted one of three ways:

- Skin electrodes. This is the most commonly used method of recording information. The skin where the electrodes will be placed is cleaned and shaved and an electrically conductive paste is applied. The electrodes are then taped in place. For female patients, the electrodes are taped around the urethra, while for male patients they are placed between the scrotum and the anus.
- Needle electrodes. This is considered the most accurate method, since the electrodes are inserted directly into the muscle, using needles to guide placement. For male patients, a gloved finger is inserted in the rectum, then needles with wires attached are inserted through the skin between the anus and the scrotum. For female patients, the needles are inserted around the urethra. The discomfort of placing the needles is about the same as that of an injection. The needles are withdrawn, and the wires are taped to the thigh.
- Anal plug electrodes. The tip of an anal plug is lubricated and inserted into the rectum as the patient relaxes the anal sphincter. Electrodes are attached to the anal plug.

Once the electrodes are in place and attached to the recording device, the patient is asked to alternately contract and relax the external sphincter muscle. The electrical activity generated during these contractions and relaxations is recorded on a graph called an electromyogram.

Preparation

Before the test, the patient should discuss with the doctor whether it is necessary to temporarily discontinue any medications, and follow the doctor's orders. No changes in diet or activity are necessary.

Aftercare

Women may see some blood in their urine the first time they urinate after the test. Blood in the urine of men or blood in the urine of women after the first urination should be reported the doctor. The patient should take a warm bath and drink plenty of fluids to ease any discomfort after the test.

Risks

Complications of external sphincter electromyography are rare. Occasionally patients report blood in their urine after being tested with needle electrodes. Also, the urethra may become mildly irritated causing a change in the normal frequency of urination.

KEY TERMS

Anti-cholinergic drug—A medication that blocks or subdues the action of the neurotransmitter acetylcholine.

Cholinergic drug—A medication that mimics or enhances the action of the neurotransmitter acetylcholine.

Sphincter—A circular muscle that aids in the opening or closing of an opening in the body.

Results

In a normally functioning external sphincter muscle, the electromyogram will show increased electrical activity when the patient tightens the muscle and a little or no electrical activity when it is relaxed.

Abnormal results

A diseased external sphincter muscle will produce an abnormal pattern of electrical activity. Conditions that affect the external sphincter may include **multiple sclerosis**, **neurogenic bladder**, Parkinson's disease, **spinal cord injury**, and stress incontinence. However, additional tests must be done in order to confirm any of these diagnoses.

Extracorporeal membrane oxygenation

Definition

Extracorporeal membrane oxygenation (ECMO) is a special procedure that uses an artificial heart-lung machine to take over the work of the lungs and sometimes also the heart.

WWW.BOOKBAZ.IR

Purpose

In newborns, ECMO is used to support or replace an infant's undeveloped or failing lungs by providing oxygen and removing carbon dioxide waste products so the lungs can rest. Infants who need ECMO may include those with:

- meconium aspiration syndrome (breathing in of a newborn's first stool by a fetus or newborn, which can block air passages and interfere with lung expansion)
- persistent pulmonary hypertension (a disorder in which the blood pressure in the arteries supplying the lungs is abnormally high)
- respiratory distress syndrome (a lung disorder usually of premature infants that causes increasing difficulty in breathing, leading to a life-threatening deficiency of oxygen in the blood)
- congenital diaphragmatic hernia (the profusion of part of the stomach through an opening in the diaphragm)
- pneumonia
- blood poisoning

ECMO also is used to support a child or adult patient's damaged, infected, or failing lungs for a few hours to allow treatment or healing. It is effective for those patients with severe, but reversible, heart or lung problems who have not responded to treatment with a ventilator, drugs, or extra oxygen. Adults and children who need ECMO usually have one of these problems:

- heart failure
- pneumonia
- respiratory failure caused by trauma or severe infection

The ECMO procedure can help a patient's lungs and heart rest and recover, but it will not cure the underlying disease. Any patient who requires ECMO is seriously ill and will likely die without the treatment. Because there is some risk involved, this method is used only when other means of support have failed.

Demographics

ECMO is used most often in newborns and young children, but it also can be used as a last resort for adults whose heart or lungs are failing.

Description

There are two types of ECMO. Venoarterial (V-A) ECMO supports the heart and lungs, and is used for patients with blood pressure or heart functioning problems in addition to respiratory problems. Venovenous (V-V) ECMO supports the lungs only.

V-A ECMO requires the insertion of two tubes, one in the jugular and one in the carotid artery. In the V-V ECMO procedure, the surgeon places a plastic tube into the jugular vein through a small incision in the neck.

Once in place, the tubes are connected to the ECMO circuit, and then the machine is turned on. The patient's blood flows out through the tube and may look very dark because it contains very little oxygen. A pump pushes the blood through an artificial membrane lung, where oxygen is added and carbon dioxide is removed. The size of the artificial lung depends on the size of the patient; sometimes adults need two lungs. The blood is then warmed and returned to the patient. A steady amount of blood (called the flow rate) is pushed through the ECMO machine every minute. As the patient improves, the flow rate is lowered. Many patients require heavy **sedation** while they are on ECMO to lessen the amount of oxygen needed by the muscles.

If the patient improves, the amount of ECMO support is decreased gradually until the machine is turned off for a brief trial period. If the patient does well without ECMO, the treatment is stopped.

Typically, newborns remain on ECMO for three to seven days, although some babies need more time (especially if they have a diaphragmatic **hernia**). Once the baby is off ECMO, he or she will still need a ventilator (breathing machine) for a few days or weeks. Adults may remain on ECMO for days to weeks, depending on the condition of the patient, but treatment may be continued for a longer time depending on the type of heart or lung disease, the amount of damage to the lungs before ECMO was begun, and the presence of any other illnesses or health problems.

Benefits

ECMO can be a life-saving procedure when time is needed for the lungs to recover.

Precautions

Typically, ECMO patients have daily chest x rays and blood work, and constant vital sign monitoring. They are usually placed on a special rotating bed that is designed to decrease pressure on the skin and help move secretions from the lungs.

After the patient is stable on ECMO, the breathing machine settings will be lowered to "rest" settings, which allow the lungs to rest without the risk of too much oxygen or pressure from the ventilator.

KEY TERMS

Carotid artery—Two main arteries (passageway carrying blood from the heart to other parts of the body) that carry blood to the brain.

Congenital diaphragmatic hernia—The profusion of part of the stomach through an opening in the diaphragm.

Meconium aspiration syndrome—Breathing in of meconium (a newborn's first stool) by a fetus or newborn, which can block air passages and interfere with lung expansion.

Membrane oxygenator—The artificial lung that adds oxygen and removes carbon dioxide.

Pulmonary hypertension—A disorder in which the blood pressure in the arteries supplying the lungs is abnormally high.

Respiratory distress syndrome—A lung disorder usually of premature infants that causes increasing difficulty in breathing, leading to a life-threatening deficiency of oxygen in the blood.

Venoarterial (V-A) bypass—The type of ECMO that provides both heart and lung support, using two tubes (one in the jugular vein and one in the carotid artery).

Venovenous (V-V) bypass—The type of ECMO that provides lung support only, using a tube inserted into the jugular vein.

Preparation

Before ECMO is begun, the patient receives medication to ease **pain** and restrict movement.

Aftercare

Because infants on ECMO may have been struggling with low oxygen levels before treatment, they may be at higher risk for developmental problems. They will need to be monitored as they grow.

Risks

Bleeding is the biggest risk for ECMO patients, since blood thinners are given to guard against **blood clots**. Bleeding can occur anywhere in the body, but is most serious when it occurs in the brain. This is why doctors periodically perform **ultrasound** brain scans of anyone on ECMO. **Stroke**, which may be caused by bleeding or blood clots in the brain, has occurred in some patients undergoing ECMO.

If bleeding becomes a problem, the patient may require frequent blood transfusions or operations to control the bleeding. If the bleeding cannot be stopped, ECMO will be withdrawn.

Other risks include infection or vocal cord injury. Some patients develop severe blood infections that cause irreversible damage to vital organs.

There is a small chance that some part of the complex equipment may fail, which could introduce air into the system or affect the patient's blood levels, causing damage or death of vital organs (including the brain). For this reason, the ECMO circuit is constantly monitored by a trained technologist.

Eye and orbit ultrasounds

Definition

Ultrasound imaging equipment allows eye specialists (ophthalmologists) to "see" the eye in great detail without the **pain** and risk of exploratory surgery, or the limitations and uncertainty inherent to traditional visual examination. Ultrasound is used to detect and diagnose many eye diseases and injuries, to measure the eye prior to corrective surgery, and directly as a treatment tool.

Purpose

An ophthalmologist uses ultrasonic imaging to help diagnose the underlying cause(s) of a patient's symptoms, to assess the general condition of an injured eye, and to measure the eye prior to corrective surgery. Situations that may call for ultrasonic imaging include:

- Excessive tearing or visible infection. These external symptoms could indicate a serious underlying problem such as a tumor, an internal infection, the presence of a deeply lodged irritant (foreign body), or the effects of a previously unrecognized injury. When presented with general symptoms, ultrasound can speed diagnosis if a serious condition is suspected.
- Impaired vision. Fuzzy vision, poor night vision, restricted (tunnel) vision, blind spots, extreme light sensitivity, and even blindness can all stem from inner eye conditions ranging from glaucoma and cataracts, to retinitis, detached retina, tumors, or impaired blood circulation. Again, high resolution ultrasound can quickly identify causes and pinpoint their location. A special type of ultrasound, known as Doppler, can even perceive and measure circulation in the tiny blood vessels of the eye.
- Eye trauma. The eye can be damaged by a direct impact or a puncture wound, as a result of a general head trauma, or by intense light exposure. Even when the cause of injury is obvious, ultrasound can reveal the exact type, extent, and location of damage, from deformations and ruptures to internal bleeding, and help to guide emergency care efforts.
- Lens replacement surgery. Exact measurement of the eye's optical dimensions with ultrasound greatly improves the visual outcome for cataract patients receiving permanent synthetic lenses; and for severely myopic patients receiving implanted corrective lenses.

Ophthalmic ultrasound imaging is also used routinely to guide the precise placement of instruments during surgery, and can be used directly for the treatment of **glaucoma** and tumors of the eye.

Precautions

Ultrasound of the eye, properly performed by qualified personnel using appropriate equipment, has no risks. There is no evidence to suggest that the procedure itself poses any threat to a healthy eye, or worsens the condition of a diseased or injured eye.

Description

Ophthalmic ultrasound equipment sends high frequency pulses of sound into the eye, where they bounce off the boundaries between different structures in the eye and produce a distinctive pattern of echoes. This echo pattern is received and interpreted by a computer to produce an image on a television screen. The time it takes an echo to return to the receiver corresponds to the depth it traveled into the eye.

Single transducer (the sound transmitter/receiver) ultrasound is used to measure distances within the eye. This is A-mode ultrasound. A linear array of transducers in a single small probe, B-mode, provides a picture of a cross section through the eye. Doppler mode ultrasound combines B-mode with the ability to detect and measure the flow of blood in the tiny vessels of the eye.

As a direct treatment tool, the vibrations of high intensity A-mode ultrasound can be used to heat and erode tumors. The same technique can be used to control glaucoma by selectively destroying the cells that produce the fluid that causes the internal pressure of the eye to rise.

The procedure followed in a regular ultrasonic **eye examination** is relatively simple. The patient relaxes in a comfortable chair in a darkened room. Mild anesthetic eye drops are administered and the head is held secure. The ultrasonic probe, coated that a sterile gel to ensure good contact, is lightly pressed against the eye as the images are made. The probe may be applied to the eyelid or directly to the eye, as necessary. The patient feels nothing else, and the whole office procedure takes about 15 minutes.

Preparation

Preparation by the patient is generally unnecessary, although under special circumstances an ophthalmologist may perform pretest procedures. The ophthalmologist and/or ultrasound technician will conduct all preparations at the time of the test.

KEY TERMS

Cataracts—A clouding of the lens of the eye or the material immediately surrounding it, causing blurred vision. For many people it occurs naturally with aging, but may also result from injury.

Glaucoma—A common eye disease characterized by increased fluid pressure in the eye that damages the optic nerve, which carries sensations to the brain. Glaucoma can be caused by another eye disorder, such as a tumor or congenital malformation, or appear without obvious cause, but if untreated it generally leads to blindness.

Intraocular—Literally, within the eye.

Ophthalmologist—A medical doctor specializing in eye care who is generally, but not necessarily, an eye surgeon.

Retina—The third and innermost membrane of the eye, which contains the light-sensitive nerve tissue that leads into the optic nerve and is the primary instument of vision. Inflammation of the retina (retinitis) has many causes, including over-exposure to intense light, diabetes, and syphilis.

Aftercare

Patients may experience partial and temporary blurred vision, as well as "eye strain" headaches. These symptoms usually fade within an hour of the procedure, during which time patients should rest their eyes and avoid all activities that require good eyesight, like driving.

Risks

Improperly focused, high-intensity ultrasound could burn and physically disrupt delicate eye tissue and cause injury. This risk is slight and would arise only from improper use, or as a potential side effect of tumor or glaucoma treatment.

Results

A normal ultrasound scan would indicate a fully healthy eye. For therapeutic ultrasound, a normal result would be an improvement in the targeted condition, such as shrinking of a tumor or lessening of pressure inside the eye of a glaucoma patient.

Abnormal results

Because diagnostic ultrasound is generally used to investigate symptoms, the results of a scan will often be abnormal and they will detect evidence of an underlying condition.

Kurt Richard Sternlof

Eye cancer

Definition

Eye cancer refers to a cancerous growth in any part of the eye. Some eye cancers are considered to be primary tumors, indicating the tumor originated in the eye or the orbit of the eye. Other eye cancers represent metastases from primary cancers elsewhere in the body. The most common type of primary intraocular cancer in adults is intraocular **melanoma** or melanoma of the eye. The most common type of eye cancer affecting children is **retinoblastoma**.

Demographics

All types of eye cancer are rare in comparison to other cancerous tumors. According to the American Cancer Society, 2,480 people in the United States will be diagnosed with cancer of the eye or orbit in 2010, and 230 persons will die from the disease. Most of these cases of eye cancer will be caused by melanoma. Lymphomas are the second most common tumors of the eye in adults. Most cases of melanoma and lymphomas of the eye begin elsewhere in the body.

Retinoblastoma in children is an extremely rare type of cancer in the United States with about 300 new cases diagnosed each year. The average age at diagnosis is two years of age. This type of cancer is rarely diagnosed in children older than age six. Most of the time the cancer is confined to one eye. In about one–third of cases, tumors affect both eyes.

Description

Eye cancers can be grouped into three basic categories according to their location in the eye: tumors of

WWW.BOOKBAZ.IR

the eyelid and conjunctiva; intraocular tumors; and orbital tumors. Retinoblastoma is the most common eye cancer in children, and intraocular melanoma is the most common eye cancer in adults.

Retinoblastoma typically begins as a small tumor in the retina, the tissue that lies at the very back of the eye. In growing children, the retina originates from cells called retinoblasts that grow and divide very quickly. These cells eventually become the mature cells of the retina when they stop growing. In the case of retinoblastoma the retinoblasts do not stop growing but, instead, form a tumor that can continue to grow and cause further complications if not treated quickly.

Retinoblastoma typically has three classifications: intraocular, extraocular, and recurrent retinoblastoma. In the intraocular form the cancer can be found in one or both eyes but not in tissue external to the eye. In the extraocular form the cancer has spread outside the eye. It can spread to the tissue surrounding the eye or it can invade other areas of the body. In the recurrent form the cancer returns after previously being treated. It may recur in the eye, its surrounding tissues, or elsewhere in the body.

Intraocular melanoma is a rare cancer overall, yet it is the most common eye cancer seen in adults. Intraocular melanoma occurs when cancer cells are found in the uvea of the eye. The uvea includes the iris (the colored portion of eye), the ciliary body (an eye muscle that focuses the lens) and the choroid (found in the back of the eye next to the retina).

Intraocular cancer of the iris usually grows slowly and usually does not spread. The tumor is seen on the iris as a spot that is darker than the surrounding area. Intraocular cancer of the choroid or ciliary body occurs in the back of the eye. This type of cancer is classified by size with a small tumor being 2–3 mm or smaller and a medium or large tumor being larger than 3 mm.

Intraocular cancer can spread and become extraocular as well. If not found and treated early enough it can spread to surrounding tissues, the optic nerve or into the orbit (eye socket).

Causes and symptoms

The causes of intraocular melanoma are not yet fully understood. Individuals who appear to be at high risk for the development of intraocular melanoma include:

- individuals with light skin and eye color
- people diagnosed with dysplastic nevus syndrome
- people with abnormal brown spots in the uvea of the eye
- individuals who have been exposured to the sun and/or sunlamps

The symptoms of this type of cancer usually begin with blurred vision and tenderness of the eye. Other symptoms include appearance of floaters in the eye and changes in the position of the eyeball in the eye socket. Advanced symptoms may include loss of vision. Most of the time, these symptoms are painless. If symptoms persist a person should make an appointment with an eye specialist.

About 75% of cases of retinoblastoma are of the non–hereditary or sporadic type. This type of retinoblastoma affects only one eye.

A form of hereditary or congenital retinoblastoma has been identified. This form of retinoblastoma is also referred to as bilateral retinoblastoma because most of the cases involve cancer in both eyes. However, about 15% of cases of hereditary or congenital retinoblastoma occur in one eye only.

Signs and symptoms associated with retinoblastoma include:

- leukocoria or white papillary reflex, also referred to as cat's eye reflex, the most common sign observed at time of diagnosis
- strabismus, or improper alignment of the eyes, the second most common finding
- poor vision
- red, painful eyes
- white spots on the iris
- orbital inflammation
- glaucoma
- retinal detachment

Diagnosis

The diagnosis of eye cancer is usually made by an ophthalmologist, a doctor who specializes in treating eye disorders. In the case of cancerous growths, the doctor is usually able to see the tumor through the pupil or directly on the iris if the cancer is intraocular melanoma of the iris. Because the doctor can usually readily see the tumor a biopsy is rarely needed.

An **ultrasound** or a fluorescein **angiography** are two tests doctors use to further diagnose eye cancers. In an ultrasound, sound waves are pointed at the tumor and, depending on how they reflect off the tumor, the doctor can better diagnose the disorder. In a fluorescein angiography a fluorescent dye is injected into the patient's arm. When this dye

KEY TERMS

Brachytherapy—A type of radiation treatment for cancer in which the source of the radiation is applied directly to the surface of the body.

Carcinogen—A substance that is known to cause cancer.

Conjunctiva—The thin membrane that lines the eyelids.

Cornea—The transparent front portion of the exterior cover of the eye.

Enucleation—Surgical removal of the eyeball.

Iris (plural, irides)—The circular pigmented membrane behind the cornea of the eye that gives the eye its color. The iris surrounds a central opening called the pupil.

Ocular melanoma—A malignant tumor that arises within the structures of the eye. It is the most common eye tumor in adults.

Ophthalmology—The branch of medicine that deals with the diagnosis and treatment of eye disorders.

Orbit—The bony cavity that contains the eyeball.

Pupil—The opening in the center of the iris of the eye that allows light to enter the eye.

Uvea—The middle of the three coats of tissue surrounding the eye, comprising the choroid, iris, and ciliary body. The uvea is pigmented and well supplied with blood vessels.

circulates through the body and reaches the eye a series of rapid pictures are taken through the pupil. The tumor will show up in these photos.

Most retinoblastomas can be diagnosed as part of a detailed **eye examination** by an experienced ophthalmologist. Once a diagnosis is confirmed, imaging tests such as ultrasound, CT or MRI scans, and bone scans may be ordered to help to determine the size of the tumor and to ascertain to what extent the cancer has spread.

Treatment

The modalities used to treat intraocular melanoma depend on the size of the tumor and on how far the tumor has spread. If the tumor is in the advanced stages and there is little hope of regaining vision, the most effective treatment is an enucleation, the removal of the eye. Enucleation is a drastic treatment option and is avoided if possible. Other eye surgeries include the following:

- choroidectomy: removal of part of the choroid
- iridectomy: removal of part of the iris
- iridocyclectomy: removal of parts of the ciliary body and parts of iris
- iridotrabeculectomy: removal of parts of the supporting tissues around the cornea and iris

In cases in which the tumor is small and there is a good chance that vision will be restored, less drastic measures than the above surgeries are taken. Radiation and **chemotherapy** are two courses of treatment that may help to destroy an existing tumor and prevent its spread to other areas of the body. **Radiation therapy** can utilize external beam radiation therapy or brachytherapy approaches. Most cases of intraocular melanoma respond poorly to chemotherapy, however.

The most common type of laser treatment used for intraocular melanoma is transpupillary thermotherapy. This procedure uses infrared light to heat and destroy the tumor in one to three treatment sessions in most people.

Treatment for retinoblastoma is best performed by health care providers who are experienced in the care of young children with this very rare type of cancer. Most of the time the most experienced practitioners can be found at major children's cancer centers and hospitals.

The treatment options for retinoblastoma depend on the stage of the cancer and can include one or more of the following modalities:

- surgery, which may include enucleation of one or both eyes if the tumor is large and/or if vision has been permanently destroyed
- radiation therapy utilizing brachytherapy or external beam radiation therapy
- photocoagulation, a procedure which employs the use of lasers to treat patients with small tumors
- cryotherapy, a treatment that utilizes probes that have been frozen to very low temperatures. The probes freeze and destroy small tumors.
- thermotherapy, which utilizes heat to kill small tumors

WWW.BOOKBAZ.IR

- chemotherapy, which may be used to reduce the size of large tumors before other treatment modalities are used. A common chemotherapy regimen used in the treatment of retinoblastoma is a combination of the-drugs carboplatin and vincristine. Other chemotherapy drugs that may be utilized include cisplatin, etoposide, teniposide, cyclophosphamide, and doxorubicin.

Prognosis

Most forms of retinoblastoma and intraocular melanoma are treatable. Enucleation can usually be avoided if the tumor is found early enough. In addition, primary cancers of the eye have a relatively low mortality rate if treated promptly.

Up to 90% of children diagnosed with retinoblastoma can be cured if the cancer is diagnosed and treated in early stages.

Prevention

Retinoblastoma is not considered a preventable disease. Individuals with hereditary or congenital retinoblastoma diagnosed in family members should notify their health care providers and may be monitored more frequently to detect any early signs of disease.

As intraocular melanoma is diagnosed more frequently in individuals with light skin and eyes, these individuals should have frequent eye exams conducted by experienced ophthalmologists. Minimizing exposure to the sun and to artificial sources of sunlight such as **tanning** beds and sunlamps is also recommended to decrease the possibility for development of intraocular melanoma. Individuals with abnormal brown spots on the uvea of the eye should also be closely monitored by experienced ophthalmologists for any changes that would indicate a progression to a cancerous tumor in the eye.

Eye examination

Definition

An eye examination is a series of tests that measure a person's ocular health and visual status, to detect abnormalities in the components of the visual system, and to determine how well the person can see.

Purpose

An eye examination is performed by an ophthalmologist, (M.D. or D.O., doctor of **osteopathy**), or an optometrist (O.D.) to determine if there are any pre-existing or potential vision problems. Eye exams may also reveal the presence of many non-eye diseases. Many systemic diseases can affect the eyes, and since the blood vessels on the retina are observed during the exam, certain problems may be uncovered (e.g., high blood pressure or diabetes).

A woman looking through a refractor. *(John Greim/Photo Researchers, Inc.)*

Infants should be examined by a physician to detect any physical abnormalities. Frequency of eye exams then generally differs with age and the health of the person. Eye exams can be performed in infants, and if a problem is noted the infant can be seen, generally by a pediatric ophthalmologist. A child with no symptoms should have an eye exam at age three. Early exams are important because permanent decreases in vision (e.g., **amblyopia**, also called lazy eye) can occur if not treated early (usually by ages 6–9). Again, with no other symptoms, the second exam should take place before first grade. After first grade, the American Optometric Association recommends an eye exam every two years; ages 19–40, every two to three years; ages 41–60, every two years; and annually after that. These are recommendations for healthy people with no risk factors. Patients should ask their doctors how often they should come for exams. Some patients have risk factors for eye disease (e.g., people with diabetes or a family history of eye disease; African Americans, who are at higher risk for **glaucoma**) and may need more frequent checkups. Also, if children seem to be having trouble in school, problems with reading, rubbing their eyes when reading, etc., an eye exam may be necessary sooner.

Precautions

The examiner needs to know if the patient is taking any medications or has any existing health conditions. Some medications, even over-the-counter (OTC) medications can affect vision or even interfere with the eyedrops the doctor may use during the exam. Certain eyedrops would not be used if the patient has **asthma**, heart problems, or other conditions.

The patient may need someone to drive them home in case the eyes were dilated. Bringing sunglasses to the exam may also help decrease the glare from light until the dilating drops wear off.

Description

An eye examination, given by an ophthalmologist or optometrist, costs about $100. It may or may not be covered by insurance. It begins with information from the patient (case history) and continues with a set of primary tests, plus additional specialized tests given as needed, dictated by the outcomes of initial testing and the patient's age. The primary tests can be divided into two groups, those that evaluate the physical state of the eyes and surrounding areas, and those that measure the ability to see.

The order of the tests for the exam may differ from doctor to doctor, however, most exams will include the following procedures:

Information gathering and initial observations

The examiner will take eye and medical histories that include the patient's chief complaint, any past eye disorders, all medications being taken (e.g., OTC medications, **antibiotics**, and birth control pills), any blood relatives with eye disorders, and any systemic disorders the patient may have. The patient should also tell the doctor about hobbies and work conditions. This information helps in modifying prescriptions and lets the doctor know how the patient uses his or her eyes. For example, using a computer screen vs. construction work, the working distance of a computer screen may affect the prescription; the construction worker needs protective eyewear.

The patient should bring their current pair of glasses to the exam. The doctor can get the prescription from the glasses by using an instrument called a lensometer.

Visual acuity examination

Visual acuity measures how clearly the patient can see. It is measured for each eye separately, with and without the current prescription. It is usually measured with a Snellen eye chart, a poster with lines of different-sized letters, each line with a number at the side denoting the distance from which a person with normal vision can read that line. Other kinds of eye charts with identifiable figures are available for children or anyone unfamiliar with the Roman alphabet. These charts are made to be placed at a certain distance (usually 20 ft [3.3 m]) from the person being tested. At this distance, people with normal vision

WWW.BOOKBAZ.IR

can read a certain line (usually the lowest), marked the 20/20 line; these people are said to have 20/20 vision. For people who cannot read the smallest line, the examiner assigns a ratio based on the smallest line they can read. The first number (numerator) of the ratio is the distance between the chart and the patient, and the second number (denominator) is the distance where a person with normal vision would be able to read that line. The ratio 20/40 means the patient can see at 20 ft what people with normal vision can see at 40 ft away.

When a patient is unable to read any lines on the chart, they are moved closer until they can read the line with the largest letters. The acuity is still measured the same way. A ratio of 5/200 means the person being tested can see at 5 ft (1.5 m) what a normal person can see 200 ft (61 m).

When a patient cannot read the chart at all, the examiner may hold up some fingers and ask the patient to count them at various distances, and records the result as "counting fingers" at the distance of recognition. If the patient cannot count the examiner's fingers at any distance, the examiner determines if the patient can see hand movements. If so, the result is recorded as "hand movements." If not, the examiner determines if the patient can detect light from a penlight. If the patient can detect the light but not its direction, the result is recorded at "light perception." If the patient can recognize its direction, the result is recorded as "light projection." If the patient cannot detect the light at all, the result is recorded as "no light perception."

Eye movement examination and cover tests

The examiner asks the patient to look up and down, and to the right and left to see if the patient can move the eyes to their full extent. The examiner asks the patient to stare at an object, then quickly covers one eye and notes any movement in the eye that remains uncovered. This procedure is repeated with the other eye. This, and another similar cover test, helps to determine if there is an undetected eye turn or problem with fixation. The doctor may also have the patient look at a pen and follow it as it is moved close to the eyes. This checks convergence.

Iris and pupil examination

The doctor checks the pupil's response to light (if it dilates and constricts appropriately). The iris is viewed for symmetry and physical appearance. The iris is checked more thoroughly later using a slit lamp.

Refractive error determination-Refraction

The examiner will determine the refractive error and obtain a prescription for corrective lenses for people whose visual acuity is less than 20/20. An instrument called a phoropter, which the patient sits behind, is generally used (sometimes the refraction can be done with a trial frame that the patient wears). The phoropter is equipped with many lenses that allow the examiner to test many combinations of corrections to learn which correction allows the patient to see the eye chart most clearly. This is the part of the exam when the doctor usually says, "Which is better, one or two?" The phoropter also contains prisms, and sometimes the doctor will intentionally make the patient see double. This may help in determining a slight eye turn. The exam will check vision at distance and near (reading).

A prescription for corrective lenses can also be supplied by automated refracting devices, which measure the necessary refraction by shining a light into the eye and observing the reflected light. Another objective way to obtain a prescription is using a hand-held retinoscope. As in the automated method, the doctor shines a light in the patient's eyes and can determine an objective prescription. This is helpful in young children or infants.

Sometimes drops will be instilled in the patient's eyes before this part of the exam. The drops may relax accommodation so that the refraction will be more accurate. This is helpful in children and people who are farsighted.

After the refraction and other visual status tests, for example color tests or binocularity tests (can the patient see 3-D, or have depth perception), the doctor will check the health of the eyes and surrounding areas. The main instruments used are the ophthalmoscope and the slit lamp.

Ophthalmoscopic examination

These observations are best accomplished after dilating the pupils and require an ophthalmoscope. The ophthalmoscope most frequently used is a called a direct ophthalmoscope. It is a hand-held illuminated 15X multi-lens magnifier that lets the examiner view the inside back area of the eye (fundus). The retina, blood vessels, optic nerve, and other structures are examined.

Slit lamp examination

The slit lamp is a microscope with a light source that can be adjusted. This magnifies the external and some internal structures of the eyes. The lid and lid

KEY TERMS

Amblyopia—Decreased visual acuity, usually in one eye, in the absence of any structural abnormality in the eye.

Conjunctiva—The mucous membrane that covers the white part of the eyes (sclera) and lines the eyelids.

Cornea—Clear outer covering of the front of the eye.

Floaters—Translucent specks that float across the visual field, due to small objects floating in the vitreous humor.

Fundus—The inside of an organ. In the eye, refers to the back area that can be seen with the ophthalmoscope.

Glaucoma—There are many types of glaucoma. Glaucoma results in optic nerve damage and a decreased visual field and blindness if not treated. The three factors associated with glaucoma are increased IOP, a change in the optic nerve head, and changes in the visual field.

Gonioscope—An instrument used to inspect the eye (e.g., the anterior chamber). It consists of a magnifier and a lens equipped with mirrors; it's placed on the patient's cornea.

Iris—The colored ring just behind the cornea and in front of the lens that controls the amount of light sent to the retina.

Macula—The central part of the retina where the rods and cones are densest.

Ophthalmoscope—An instrument designed to view structures in the back of the eye.

Optic nerve—The nerve that carries visual messages from the retina to the brain.

Pupil—The circular opening that looks like a black hole in the middle of the iris.

Retina—The inner, light-sensitive layer of the eye containing rods and cones; transforms the image it receives into electrical messages which are then sent to the brain via the optic nerve.

Sclera—The tough, fibrous, white outer protective covering that surrounds the eye.

Slit lamp—A microscope that projects a linear slit beam of light onto the eye; allows viewing of the conjunctiva, cornea, iris, aqueous humor, lens, and eyelid.

Tonometer—An instrument that measures intraocular pressure (IOP).

Ultrasonography—A method of obtaining structural information about internal tissues and organs where an image is produced because different tissues bounce back ultrasonic waves differently.

margin, cornea, iris, pupil, conjunctiva, sclera, and lens are examined. The slit lamp is also used in contact lens evaluations. A little probe called a tonometer may be used at this time to check the pressure of the eyes. A colored eyedrop may be instilled immediately prior to this test. The drop has a local anesthetic so the patient will not feel the probe touch the eye. It is a quick procedure.

Visual field measurement

A perimeter, the instrument for measuring visual fields, is a hollow hemisphere, equipped with a light source that projects dots of light over the inside surface. The patient's head is positioned so that the eye being tested is at the center of the sphere and (about 13 in [33 cm]) from all points on the inside surface of the hemisphere. The patient stares straight ahead at an image on the center of the surface and signals whenever he or she detects a flash of light. The perimeter records which flashes are seen and which are missed and maps the patient's field of vision and blindspots.

Intraocular pressure (IOP) measurement

Tonometers are used to measure IOP. Some tonometers measure pressure by expelling a puff of air (noncontact tonometer) towards the eyeball from a very short distance. Other tonometers are placed directly on the cornea. The noncontact tonometers are not as accurate as the contact tonometers and are sometimes used for screenings.

Completing the evaluation with additional tests

Depending upon the results other tests may be necessary. These can include, but are not limited to binocular indirect ophthalmoscopy, gonioscopy, color tests, contrast sensitivity testing, ultasonography, and others. The patient may have to return for additional visits.

WWW.BOOKBAZ.IR

Results

External observations

INITIAL OBSERVATIONS AND SLIT LAMP EXAM. Some general observations the doctor may be looking for include: head tilt; drooping eyelids (**ptosis**); eye turns; red eyes (injection); eye movement; size, shape, and color of the iris; clarity of the cornea, anterior chamber, and lens. The anterior chamber lies behind the cornea and in front of the iris. If it appears cloudy or if cells can be seen in it during the slit lamp exam an inflammation may be present. A narrow anterior chamber may put the patient at risk for glaucoma. A clouding of the normally clear lens is called a cataract.

Internal observations

OPHTHALMOSCOPIC EXAM. The observations include, but are not limited to the retina, blood vessels, and optic nerve. The optic nerve enters the back of the eye and can be checked for swelling or other problems. The blood vessels can be viewed as can the retina. The macula is a 3–5 mm area in the back of the eye and is responsible for central vision. The fovea is a small area located within the macula and is responsible for sharp vision. When a person looks at something, they are pointing the fovea at the object. Changes in the macular area can be observed with the ophthalmoscope. Retinal tears or detachments can also be seen.

Visual ability

VISUAL ACUITY. The refraction will determine the refractive status for each eye for distance and for near. A prescription for glasses is made after taking many things into consideration. The eye doctor may alter a prescription based upon many factors. Different materials for glasses may be suggested. For example, polycarbonate may be suggested for children or people active in sports because it is very impact resistant. Bifocals, trifocals, single-vision spectacles, and **contact lenses** are also options.

VISUAL FIELDS. A normal visual field extends about 60° upward, about 75° downward, about 65° toward the nose, and about 100° toward the ear and has one blind spot close to the center. Defects in the visual field signify damage to the retina, optic nerve, or the neurological visual pathway.

Seeing clearly does not necessarily mean the eyes are healthy or that the eyes are working together as a team. Regular checkups can detect abnormalities, before a problem arises. The eye doctor can suggest ways to help protect the eyes and vision (e.g., safety goggles, ultraviolet [UV] coatings on lenses). A person should also have an eye exam if they notice a change in vision, eyestrain, blur, flashes of light, a sudden onset of floaters (little dots), distortion of objects, double vision, redness, **pain** or discharge.

Eye exercises *see* **Vision training**

Eye muscle surgery

Definition

Eye muscle surgery is surgery to weaken, strengthen, or reposition any of the muscles that move the eyeball (the extraocular muscles).

Purpose

The purpose of eye muscle surgery is generally to align the pair of eyes so that they gaze in the same direction and move together as a team, either to improve appearance or to aid in the development of binocular vision in a young child. To achieve binocular vision, the goal is to align the eyes so that the location of the image on the retina of one eye corresponds to the location of the image on the retina of the other eye.

In addition, sometimes eye muscle surgery can help people with other eye disorders (**nystagmus** and Duane syndrome, for example).

Precautions

Depth perception (stereopsis) develops around the age of three months old. For successful development of binocular vision and the ability to perceive three-dimensionally, the surgery should not be postponed past the age of four. The earlier the surgery the better the outcome, so an early diagnosis is important. Surgery may even be performed before two years old. After surgery, if binocular vision is to develop, corrective lenses and eye exercises (vision therapy) will probably be necessary.

Description

The extraocular muscles attach via tendons to the sclera (the white, opaque, outer protective covering of the eyeball) at different places just behind an imaginary equator circling the top, bottom, left, and right of the eye. The other end of each of these muscles attaches to a part of the orbit (the eye socket in the skull). These muscles enable the eyes to move up, down, to one side or the other, or any angle in between.

Normally both eyes move together, receive the same image on corresponding locations on both retinas, and the brain fuses these images into one three-dimensional image. The exception is in **strabismus** which is a disorder where one or both eyes deviate out of alignment, most often outwardly (exotropia) or toward the nose (esotropia). The brain now receives two different images, and either suppresses one or the person sees double (diplopia). This deviation can be adjusted by weakening or strengthening the appropriate muscles to move the eyes toward the center. For example, if an eye turns upward, the muscle at the bottom of the eye could be strengthened.

Rarely, eye muscle surgery is performed on people with nystagmus or Duane syndrome. Nystagmus is a condition where one or both eyes move rapidly or oscillate; it can sometimes be helped by moving the eyes to the position of least oscillation. Duane syndrome is a disorder where there is limited horizontal eye movement; it can sometimes be relieved by surgery to weaken an eye muscle.

There are two methods to alter extraocular muscles. Traditional surgery can be used to strengthen, weaken, or reposition an extraocular muscle. The surgeon first makes an incision in the conjunctiva (the clear membrane covering the sclera), then puts a suture into the muscle to prevent it from getting lost and loosens the muscle from the eyeball with a surgical hook. During a resection, the muscle is detached from the sclera, a piece of muscle is removed so the muscle is now shorter, and the muscle is reattached to the same place. This strengthens the muscle. In a recession, the muscle is made weaker by repositioning it. More than one extraocular eye muscle might be operated on at the same time.

Another way of weakening eye muscles, using botulinum toxin injected into the muscle, was introduced in the early 1980s. Although the botulinum toxin wears off, the realignment may be permanent, depending upon whether neurological connections for binocular vision were established during the time the toxin was active. This technique can also be used to adjust a muscle after traditional surgery.

KEY TERMS

Botulinum toxin (botulin)—A neurotoxin made by *Clostridium botulinum*; causes paralysis in high doses, but is used medically in small, localized doses to treat disorders associated with involuntary muscle contraction and spasms, in addition to strabismus.

Conjunctiva—The mucous membrane that covers the eyes and lines the eyelids.

Extraocular muscles—The muscles (lateral rectus, medial rectus, inferior rectus, superior rectus, superior oblique, and inferior oblique) that move the eyeball.

Orbit—The cavity in the skull containing the eyeball; formed from seven bones: frontal, maxillary, sphenoid, lacrimal, zygomatic, ethmoid, and palatine.

Retina—The inner, light-sensitive layer of the eye containing rods and cones; transforms the image it receives into electrical messages sent to the brain via the optic nerve.

Sclera—The tough, fibrous, white outer protective covering of the eyeball.

Strabismus—A disorder where the two eyes do not point in the same direction.

The cost of eye muscle surgery is about $2,000–$4,000, and about 700,000 surgeries are performed annually in the United States.

Preparation

Patients should make sure their doctors are aware of any medications that they are taking, even over-the-counter medications. Patients should not take **aspirin**, or any other blood-thinning medications for ten days prior to surgery, and should not eat or drink after midnight the night before.

Aftercare

Patients will need someone to drive them home after their surgery. They should continue to avoid aspirin and other non-steroidal anti-inflammatory agents for an additional three days, but they can take **acetaminophen** (e.g., Tylenol). Patients should discuss this with the surgeon to be clear what medications they can or cannot take. **Pain** will subside after two to three days, and patients can resume most normal activities within a few days. Again, this may vary

WWW.BOOKBAZ.IR

with the patient and the patient should discuss returning to normal activity with the surgeon. They should not get their eyes wet for three to four days and should refrain from swimming for 10 days. Operated eyes will be red for about two weeks.

Risks

As with any surgery, there are risks involved. Eye muscle surgery is relatively safe, but very rarely a cut muscle gets lost and can not be retrieved. This, and other serious reactions, including those caused by anesthetics, can result in vision loss in the affected eye. Occasionally, retinal or nerve damage occurs. Double vision is not uncommon after eye muscle surgery. Glasses or vision therapy may be necessary.

Results

Cosmetic improvement is likely with success rate estimates varying from about 65–85%. According to the best statistics, binocular vision is improved in young children about 35% of the time. There is no improvement, or the condition worsens 15–35% of the time. A second operation may rectify less-than-perfect outcomes.

Eye training *see* **Vision training**

Eyeglasses and contact lenses

Definition

Eyeglasses and contact lenses are devices that correct refractive errors in vision. Eyeglass lenses are mounted in frames worn on the face, sitting mostly on the ears and nose, so that the lenses are positioned in front of the eyes. Contact lenses appear to be worn in direct contact with the cornea, but they actually float on a layer of tears that separates them from the cornea.

Purpose

The purpose of eyeglasses and contact lenses is to correct or improve the vision of people with nearsightedness (**myopia**), farsightedness (**hyperopia**), **presbyopia**, and **astigmatism**.

Precautions

People allergic to certain plastics should not wear contact lenses or eyeglass frames or lenses manufactured from that type of plastic. People allergic to nickel should not wear Flexon frames. People at risk of being in accidents that might shatter glass lenses should wear plastic lenses, preferably polycarbonate. (Lenses made from polycarbonate, the same type of plastic used for the space shuttle windshield, are about 50 times stronger than other lens materials.) Also, people at risk of receiving electric **shock** should avoid metal frames.

People employed in certain occupations may be prohibited from wearing contact lenses, or may be required to wear safety eyewear over the contact lenses. Some occupations, such as construction or auto repair, may require safety lenses and safety frames. Physicians and employers should be consulted for recommendations.

Description

Eyes are examined by optometrists (O.D.) or by ophthalmologists (M.D. or D.O., doctor of **osteopathy**). Prescriptions, if necessary, are then given to patients for glasses. The glasses are generally made by an optician. A separate contact lens-fitting exam is necessary if the patient wants contact lenses, because an eyeglass prescription is not the same as a contact lens prescription.

Eyeglasses

More than 140 million people in the United States wear eyeglasses. People whose eyes have refractive errors do not see clearly without glasses, because the light emitted from the objects they are observing does not come into focus on their retinas. For people who are farsighted, images come into focus behind the retina; for people who are nearsighted, images come into focus in front of the retina.

LENSES. Lenses work by changing the direction of light so that images come into focus on the retina. The greater the index of refraction of the lens material and the greater the difference in the curvature between the two surfaces of the lens, the greater the change in

direction of light that passes through it, and the greater the correction.

Lenses can be unifocal, with one correction for all distances, or they can correct for more than one distance (multifocal). One type of multifocal, the bifocal, has an area of the lens (usually at the bottom) that corrects for nearby objects (about 14 in [35.5 cm] from the eyes); the remainder of the lens corrects for distant objects (about 20 ft [6 m] from the eyes). Another type of multifocal, a trifocal, has an area in-between that corrects for intermediate distances (usually about 28 in [71 cm]). Conventional bifocals and trifocals have visible lines between the areas of different correction; however, lenses where the correction gradually changes from one area to the other, without visible lines, have been available since the 1970s. Such lenses are sometimes called progressives or no-line bifocals.

To be suitable for eyeglass lenses, a material must be transparent, without bubbles, and have a high index of refraction. The greater the index of refraction, the thinner the lens can be. Lenses are made from either glass or plastic (hard resin). The advantage of plastic is that it is lightweight and more impact resistant than glass. The advantage of glass is that it is scratch resistant and provides the clearest possible vision.

Glass was the first material to be used for eyeglass lenses, and was used for several hundred years before plastic was introduced.

Optical-quality acrylic was introduced for eyeglass use in the early 1940s, but because it was easily scratched, brittle, and discolored rapidly, it did not supplant glass as the material of choice. Furthermore, it was not suitable for people with large refractive errors. A plastic called CR-39, introduced in the 1960s, was more suitable. Today, eyeglass wearers can also choose between polycarbonate, which is the most impact-resistant material available for eyewear, and polyurethane, which has exceptional optical qualities and higher refraction than the conventional plastics even glass. Patients with high prescriptions should ask about high index material options for their lenses. Aspheric lenses are also useful for high prescriptions. They are flatter and lighter than conventional lenses.

There are many lenses and lens-coating options for individual needs, including coatings that block the ultraviolet (UV) light or UV and blue light, which have been found to be harmful to the eyes. Such coatings are not needed on polycarbonate lenses, which already have UV protection. UV coatings are particularly important on sunglasses and ski goggles. Sunglasses, when nonprescription, should be labeled with an indication that they block out 99–100% of both UV-A and UV-B rays.

There are anti-scratch coatings that increase the surface hardness of lenses (an important feature when using plastic lenses) and anti-reflective (AR) coatings that eliminate almost all glare and allow other people to see the eyes of the wearer. AR coatings may be particularly helpful to people who use computers or who drive at night. Mirror coatings that prevent other people from seeing the wearer's eyes are also available. There is a whole spectrum of tints, from light tints to darker tints, used in sunglasses. Tint, however, does not block out UV rays, so a UV coating is needed. Polaroid lenses that block out much of the reflected light also allow better vision in sunny weather and are helpful for people who enjoy boating. Photosensitive (photochromatic) lenses that darken in the presence of bright light are handy for people who do not want to carry an extra set of glasses. Photochromatic lenses are available in glass and plastic.

FRAMES. Frames can be made from metal or plastic, and they can be rimless. There is an almost unlimited variety of shapes, colors, and sizes. The type and degree of refractive correction in the lens determine to some extent the type of frame most suitable. Some lenses are too thick to fit in metal rims, and some large-correction prescriptions are best suited to frames with small-area lenses.

Rimless frames are the least noticeable type, and they are lightweight because the nosepiece and temples are attached directly to the lenses, eliminating the weight of the rims. They tend to not be as sturdy as frames with rims, so they are not a good choice for people who frequently remove their glasses and put them on again. They are also not very suitable for lenses that correct a high degree of farsightedness, because such lenses are thin at the edges.

Metal frames are less noticeable than plastic, and they are lightweight. They are available in solid gold, gold-filled, anodized aluminum, nickel, silver, stainless steel, and now titanium and titanium alloy. Until the late 1980s, when titanium-nickel alloy and titanium frames were introduced, metal frames were, in general, more fragile than plastic frames. The titanium frames, however, are very strong and lightweight. An alloy of titanium and nickel, called Flexon, is not only strong and lightweight, but returns to its original shape after being twisted or dented. It is not perfect for everyone, though, because some people are sensitive to its nickel. Flexon frames are also relatively expensive.

Plastic frames are durable, can accommodate just about any lens prescription, and are available in a wide range of prices. They are also offered in a variety of plastics (including acrylic, epoxy, cellulose

WWW.BOOKBAZ.IR

acetate, cellulose propionate, polyamide, and nylon) and in different colors, shapes, and levels of resistance to breakage. Epoxy frames are resilient and return to their original shape after being deformed, so they do not need to be adjusted as frequently as other types. Nylon frames are almost unbreakable. They revert to their original shape after extreme **trauma** and distortion; because of this property, though, they cannot be readjusted after they are manufactured.

FIT. The patient should have the distance between the eyes (PD; pupil distance) measured, so that the optical centers of the lenses will be in front of the patient's pupils. Bifocal heights also have to be measured with the chosen frame in place and adjusted on the patient. Again, this is so the lenses will be positioned correctly. If not positioned correctly, the patient may experience eyestrain or other problems. This can occur with over-the-counter reading glasses. The distance between the lenses is for a "standard" person. Generally, this will not be a problem, but if a patient is sensitive or has more closely set eyes, for example, it may pose a problem. Persons buying ready-made sunglasses or reading glasses should hold them up to see if they appear clear. They should also hold the lenses to see an object with straight lines reflected off of the lenses. If the lines do not appear straight, the lenses may be warped or inferior.

Patients may sometimes need a few days to adjust to a new prescription; however, problems should be reported, because the glasses may need to be rechecked.

Contact lenses

More than 32 million people in the United States wear these small lenses that fit on top of the cornea. They provide a field of view unobstructed by eyeglass frames; they do not fog up or get splattered, so it is possible to see well while walking in the rain; and they are less noticeable than any eyeglass style. On the other hand, they take time to get accustomed to; require more measurements for fitting; require many follow-up visits to the eye doctor; can lead to complications such as infections and corneal damage; and may not correct astigmatism as well as eyeglasses, especially if the astigmatism is severe.

Originally, hard contact lenses were made of a material called PMMA. Although still available, the more common types of contact lenses are listed below:

- Rigid gas-permeable (RGP) daily-wear lenses are made of plastic that does not absorb water but allows oxygen to get from the atmosphere to the cornea. (This is important because the cornea has no blood supply and needs to get its oxygen from the atmosphere through the film of tears that moves beneath the lens.) They must be removed and cleaned each night.
- Rigid gas-permeable (RGP) extended-wear lenses are made from plastic that also does not absorb water but is more permeable to oxygen than the plastic used for daily-wear lenses. They can be worn up to a week.
- Daily wear soft lenses are made of plastic that is permeable to oxygen and absorbs water; therefore, they are soft and flexible. These lenses must be removed and cleaned each night, and they do not correct all vision problems. Soft lenses are easier to get used to than rigid lenses, but are more prone to tears and do not last as long.
- Extended-wear soft lenses are highly permeable to oxygen, are flexible by virtue of their ability to absorb water, and can usually be worn for up to one week. They do not correct all vision problems. There is more of a risk of infection with extended-wear lenses than with daily-wear lenses.
- Extended-wear disposable lenses are soft lenses worn continually for up to six days and then discarded, with no need for cleaning.
- Planned-replacement soft lenses are daily wear lenses that are replaced on a regular schedule, which is usually every two weeks, monthly, or quarterly. They must also be cleaned.

Soft contact lenses come in a variety of materials. There are also different kinds of RGP and soft multifocal contact lenses available. Monovision, where one contact lens corrects for distance vision while the other corrects for near vision, may be an option for presbyopic patients. Monovision, however, may affect depth perception and may not be appropriate for everyone. Contact lenses also come in a variety of tints. Soft contacts are available that can make eyes appear a different color. Even though such lenses have no prescription, they must still be fitted and checked to make sure that an eye infection does not occur. People should never wear someone else's contact lenses. This can lead to infection or damage to the eye.

Tiny, surgically implanted contact lenses may one day replace eyeglasses, contact lenses and **laser surgery** for some patients with extreme nearsightedness. Aspheric intraocular lenses (IOLs) were approved by the FDA in 2004. Several types of IOLs are available specific to the patient's optical needs.

KEY TERMS

Astigmatism—Assymetric vision defects due to irregularities in the cornea.

Cornea—The clear outer covering of the front of the eye.

Index of refraction—A constant number for any material for any given color of light that is an indicator of the degree of the bending of the light caused by that material.

Lens—A device that bends light waves.

Permeable—Capable of allowing substances to pass through.

Polycarbonate—A very strong type of plastic often used in safety glasses, sport glasses, and children's eyeglasses. Polycarbonate lenses have approximately 50 times the impact resistance of glass lenses.

Polymer—A substance formed by joining smaller molecules. For example, plastic, acrylic, cellulose acetate, cellulose propionate, nylon, etc.

Presbyopia—A condition affecting people over the age of 40 where the system of accommodation that allows focusing of near objects fails to work because of age-related hardening of the lens of the eye.

Retina—The inner, light-sensitive layer of the eye containing rods and cones; transforms the image it receives into electrical messages sent to the brain via the optic nerve.

Ultraviolet (UV) light—Part of the electromagnetic spectrum with a wavelength just below that of visible light. It is damaging to living material, especially eyes and DNA.

Aftercare

Contact lens wearers must be examined periodically by their eye doctors to make sure that the lenses fit properly and that there is no infection. Infection and lenses that do not fit properly can damage the cornea. Patients can be allergic to certain solutions that are used to clean or lubricate the lenses. For that reason, patients should not randomly switch products without speaking with their doctor. Contact lens wearers should seek immediate attention if they experience eye **pain**, a burning sensation, red eyes, intolerable sensitivity to light, cloudy vision, or an inability to keep the eyes open.

To avoid infection, it is important for contact lens wearers to exactly follow their instructions for lens insertion and removal, as well as cleaning. Soft contact lens wearers should never use tap water to rinse their lenses or to make up solutions. All contact lens wearers should also always have a pair of glasses and a carrying case for their contacts with them, in case the contacts have to be removed due to eye irritation.

Risks

Wearing contact lenses increases the risk of corneal damage and eye infections.

Results

The normal expectation is that people will achieve 20/20 vision while wearing corrective lenses. A new technology for customized eyeglasses patented in 2004 claims to achieve exceptional vision assessment and 20/10 acuity by using wavefront measurements and precise parameters to produce measurements such as pupil size and distance, along with other customized lens and frame features.

Eyelid disorders

Definition

An eyelid disorder is any abnormal condition that affects the eyelids.

Description

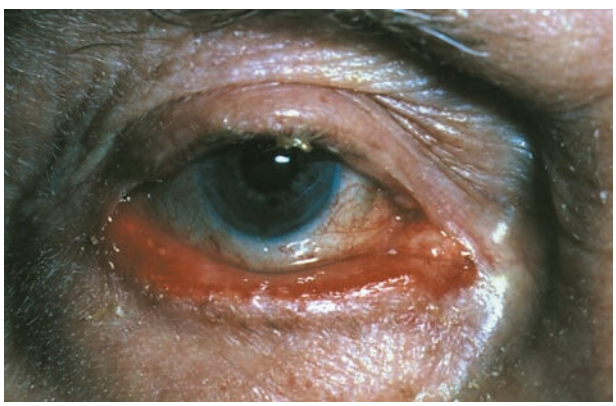
Eyelids consist of thin folds of skin, muscle, and connective tissue. The eyelids protect the eyes and spread tears over the front of the eyes. The inside of the eyelids are lined with the conjunctiva of the eyelid (the palpebral conjunctiva), and the outside of the lids are covered with the body's thinnest skin. Some common lid problems include the following: stye, blepharitis, chalazion, entropion, ectropion, eyelid **edema**, and eyelid tumors.

Stye

A stye is an infection of one of the three types of eyelid glands near the lid margins, at the base of the lashes.

Chalazion

A chalazion is an enlargement of a meibomian gland (an oil-producing gland in the eyelid), usually not associated with an infectious agent. More likely, the gland opening is clogged. Initially, a chalazion may resemble a stye, but it usually grows larger. A chalazion may also be located in the middle of the lid and be internal.



A close-up of the eye of an elderly patient showing ectropion of the lower eyelid. Ectropion is a condition in which the eyelid turns away from the eye. Ectropion is a condition in which the eyelid turns away from the eye. The most common type is senile ectropion (seen here), in which the droop of the eyelid is due to loss of tissue elasticity in old age and weakness in the muscles surrounding the eye. *(Dr. P. Marazzi/ Photo Researchers, Inc.)*

Blepharitis

Blepharitis is the inflammation of the eyelid margins, often with scales and crust. It can lead to eyelash loss, chalazia, styes, ectropion, corneal damage, excessive tearing, and chronic **conjunctivitis**.

Entropion

Entropion is a condition where the eyelid margin (usually the lower one) is turned inward; the eyelashes touch the eye and irritate the cornea.

Ectropion

Ectropion is a condition where one or both eyelid margins turn outward, exposing both the conjunctiva that covers the eye and the conjunctiva that lines the eyelid.

Eyelid edema

Eyelid edema is a condition where the eyelids contain excessive fluid.

Eyelid tumors

Eyelids are susceptible to the same skin tumors as the skin over the rest of the body, including noncancerous tumors and cancerous tumors (**basal cell carcinoma**, squamous cell carcinoma, malignant **melanoma**, and sebaceous gland carcinoma). Eyelid muscles are susceptible to sarcoma.

Causes and symptoms

Stye

Styes are usually caused by bacterial **staphylococcal infections**. The symptoms are **pain** and inflammation in one or more localized regions near the eyelid margin.

Chalazion

A chalazion is caused by a blockage in the outflow duct of a meibomian gland. Symptoms are inflammation and swelling in the form of a round lump in the lid that may be painful.

Blepharitis

Some cases of blepharitis are caused by bacterial infection and some by head lice, but in some cases, the cause is unclear. It may also be caused by an overproduction of oil by the meibomian glands. Blepharitis can be a chronic condition that begins in early childhood and can last throughout life. Symptoms can include **itching**, burning, a feeling that something

A chalazion on the eyelid. This condition is caused by an obstruction of one of the meibomian glands that lubricate the edge of the eyelid. *(Photo Researchers, Inc.)*

is in the eye, inflammation, and scales or matted, hard crusts surrounding the eyelashes.

Entropion

Entropion usually results from **aging**, but sometimes can be due to a congenital defect, a spastic eyelid muscle, or a scar on the inside of the lid from surgery, injury, or disease. It is accompanied by excessive tearing, redness, and discomfort.

Ectropion

Similar to entropion, the usual cause of ectropion is aging. It also can be due to a spastic eyelid muscle or a scar, as in entropion. It also can be the result of **allergies**. Symptoms are excessive tearing and hardening of the eyelid conjunctiva.

Eyelid edema

Eyelid edema is most often caused by allergic reactions, for example, allergies to eye makeup, eyedrops or other drugs, or plant allergens such as pollen. **Trichinosis**, a disease caused by eating undercooked meat, also causes eyelid edema. However, swelling can also be caused by more serious causes, such as infection, and can lead to **orbital cellulitis**, which can threaten vision. Symptoms can include swelling, itching, redness, or pain.

Eyelid tumors

Tumors found on the eyelids are caused by the same conditions that cause these tumors elsewhere on the body. They are usually painless and may or may not be pigmented. Some possible causes include **AIDS** (Kaposi's sarcoma) or increased exposure to ultraviolet (UV) rays that may lead to **skin cancer**.

Diagnosis

An instrument called a slit lamp is generally used to magnify the structures of the eyes. The doctor may press on the lid margin to see if oil can be expressed from the meibomian glands. The doctor may invert the lid to see the inside of the lid. Biopsy is used to diagnose cancerous tumors.

Treatment

Stye

Styes are treated with warm compresses for 10–15 minutes, three to four times a day. Chloramphenicol ointment may be used as well. Sometimes **topical antibiotics** may be prescribed if the infection is spreading.

Chalazion

About 25% of chalazia will disappear spontaneously, but warm compresses may speed the process. Chloramphenicol ointment may be used as well. Because chalazia are inside the lid, topical medications are generally of no benefit. Medication may need to be injected by the doctor into the chalazion or, if that does not help, the chalazion may need to be excised. If what appears to be a chalazion recurs on the same site as any previous one, the possibility of sebaceous gland carcinoma should be investigated by biopsy.

Blepharitis

Blepharitis is treated with hot compresses, with antibiotic ointment, and by cleaning the eyelids with a moist washcloth and then with baby shampoo. Good hygiene is essential. Patients can try to keep rooms dry, such as by placing a bowl of water on top of a radiator. Tear film supplements such as hypromellose can help moisten the eyes when dry. If itching, soreness, or redness occurs from the tear film drops, they should be stopped. Topical or systemic **antibiotics** also may be prescribed. If the blepharitis does not clear up with treatment or if it seems to be a chronic problem, the patient may have **acnerosacea**. These patients may need to see a dermatologist as well.

WWW.BOOKBAZ.IR

Entropion and ectropion

Both entropion and ectropion can be surgically corrected. Prior to surgery, the lower lid of entropion can be taped down to keep the lashes off the eye, and both can be treated with lubricating drops to keep the cornea moist.

Eyelid edema

Patients with swollen eyelids should contact their eye doctor. A severely swollen lid can press on the eye and possibly increase the intraocular pressure. An infection needs to be ruled out. Something as simple as an allergy to nail polish and then touching the eyes can cause swelling. The best treatment for allergic eyelid edema is to find and remove the substance causing the allergy. When that is not possible, as in the case of plant allergens, cold compresses and immunosuppresesive drugs such as corticosteroid creams are helpful. However, **steroids** can cause **cataracts** and increase intraocular pressure and patients must be very careful not to get the cream in their eyes. This should not be done unless under a doctor's care. For edema caused by trichinosis, the trichinosis must be treated.

Eyelid tumors

Cancerous tumors should be removed upon discovery, and noncancerous tumors should be removed before they become big enough to interfere with vision or eyelid function. Eyelid tumors require special consideration because of their sensitive location. It is important that treatment not compromise vision, eye movement, or eyelid movement. Accordingly, eyelid reconstruction will sometimes accompany tumor excision.

Prognosis

The prognosis for styes and chalazia is good to excellent. With treatment, blepharitis, ectropion, and entropion usually have good outcomes. The prognosis for nonmalignant tumors, basal cell carcinoma, and squamous cell carcinoma is good once they are properly removed. Survival rate for malignant melanoma depends upon how early it was discovered and if it was completely removed. Sebaceous carcinomas are difficult to detect, so poor outcomes are more frequent.

All of these eyelid disorders, if not treated, can lead to other, possibly serious vision problems—dry eye, **astigmatism**, or even vision loss, for example. An ophthalmologist or optometrist should be consulted.

KEY TERMS

Allergen—A substance capable of inducing an allergic response.

Allergic reaction—An immune system reaction to a substance in the environment; symptoms include rash, inflammation, sneezing, itchy watery eyes, and runny nose.

Conjunctiva—The mucous membrane that covers the white part of the eyes and lines the eyelids.

Edema—A condition where tissues contain excessive fluid.

Meibomian gland—Oil-producing glands in the eyelids that open near the eyelid margins.

Prevention

Good lid hygiene is very important. Regular eyelid washing with baby shampoo helps prevent styes, chalazia, blepharitis, and eyelid edema. To avoid these problems, it is also important to refrain from touching and rubbing the eyes and eyelids, especially with hands that have not just been washed.

Blepharitis is associated with dandruff, which is caused by a kind of bacteria that is one of the causes of blepharitis. Controlling dandruff by washing the hair, scalp, and eyebrows with shampoo containing selenium sulfide to kill the bacteria helps control the blepharitis. When using anything near the eyes, it is important to read the label or consult with a doctor first.

Avoiding allergens helps prevent allergic eyelid edema. Staying inside as much as possible when pollen counts are high and eliminating the use of, or at least removing eye makeup thoroughly, or using hypoallergenic makeup may help if the person is sensitive to those substances.

Sunscreen, UV-blocking sunglasses, and wide brimmed hats can help prevent eyelid tumors.

Entropian and ectropian seem to be unpreventable.

Face lift

Definition

Face lift surgery is a cosmetic procedure that involves removing sagging skin and tightening muscle tissue of the face and neck to counter signs of **aging**. The procedure is also called facialplasty, rhytidoplasty, and cervicofacial rhytidectomy.

Purpose

The purpose of face lift surgery is to improve the appearance of the face by repositioning the skin and tightening some of the underlying muscle and tissue. The procedure is designed to counter sagging and looseness in skin and muscle tissue that becomes more pronounced as individuals age. Face lift surgery will not eliminate all facial wrinkles. For example, wrinkles around the mouth and eyes may benefit little from face lift surgery. In addition, other procedures including **blepharoplasty**, chemical peel, Botox injections, or dermabrasion may be necessary to achieve desired results.

Demographics

The American Society for Aesthetic Plastic Surgery estimated that nearly 14.6 million cosmetic surgical and nonsurgical procedures were performed in the United States in 2012, at a total cost of about $11 billion. The number of face lift procedures increased by 6% from the previous year (2011), with approximately 126,000 face lift procedures performed in 2012. The majority of patients undergoing face lifts were female, with only about 9% of all patients being male. The average fee for a face lift in 2011 was $6,500.

Description

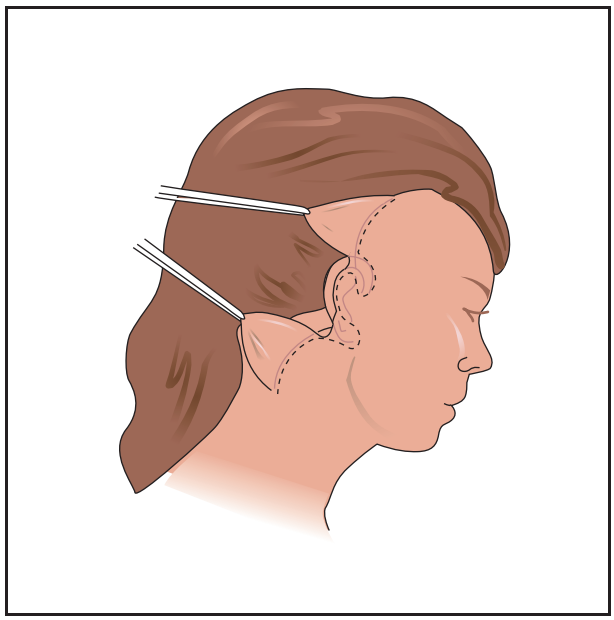
Face lifts are performed by surgeons with specialized training in plastic and **reconstructive surgery**. They are most commonly performed in outpatient facilities or in private professional offices. The procedure may also be performed in a hospital.

A face lift takes approximately two hours and may be performed as an outpatient procedure, or the patient may require hospitalization. General anesthetics or local anesthetics with possible **sedation** may be used during the procedure. Typically, patients receiving local **anesthesia** may also receive "twilight anesthesia," an intravenous sedative that helps to lower their awareness of the procedure being performed. An anesthesiologist will be present to administer the anesthetics and assist in monitoring the patient's vital life functions.

The surgeon makes an incision within the hairline just above the ear. The incision continues down along the front edge of the ear, around the earlobe, and then up and behind the ear extending back into the hairline. The location of this incision is designed to hide any sign of the procedure later. The same procedure is repeated on the other side of the face. The surgeon separates the skin of the face from its underlying tissue, moving down to the cheek and into the neck area and below the chin. Fat deposits over the cheeks and in the neck may be removed surgically or with **liposuction** at this time. The surgeon tightens certain bands of muscle and tissue that extend up from the shoulder, below the chin, and up and behind the neck. If these muscles and tissue are not tightened, the looseness and sagging appearance of the skin will return. The surgeon trims excess skin from the edges of the original incision and the skin is pulled back into place. The incision is closed with sutures or staples.

Preparation

Prior to the procedure, candidates meet with the surgeon to discuss the procedure, clarify the expected



In a typical face lift surgery, the surgeon begins by making an incision within the hairline just above the ear. The incision continues down along the front of the ear, around the earlobe, and then up and behind the ear extending back into the hairline. The same procedure is repeated on the other side of the face. The surgeon will then separate the skin from the tissue, remove fat deposits over the cheeks and neck, tighten up muscles and tissues below the chin and upwards behind the neck. The surgeon will then trim excess skin from the original incision, pull the skin back, and suture it into place. *(Illustration by Electronic Illustrators Group. © Cengage Learning®.)*

outcomes, and explain any potential problems that can occur. Having realistic expectations is important in any cosmetic procedure. People will learn, for example, that although a face lift can improve the contour of the face and neck, additional procedures may be necessary to reduce the appearance of many wrinkles. Candidates will be advised to stop taking **aspirin**, birth control pills, female hormones, or other medications that may affect blood clotting two weeks before the procedure. Some physicians prescribe vitamin C and K to promote healing. Candidates are advised to stop **smoking** and to avoid exposure to passive smoke at least two weeks before and after the procedure. Some surgeons also recommend taking **antibiotics** prior to surgery to limit the risk of infection. In addition, a steroid injection is often administered before or after the procedure to reduce swelling.

Aftercare

A pressure bandage is applied to the face to reduce the risk of hematoma, which is a pocket of blood below the skin. The patient may spend a few hours resting in a recovery room to ensure that no bleeding has occurred. The individual then returns home. Some surgeons recommend that people stay in a reclining position for the 24 hours immediately following surgery, consume a liquid diet, and avoid flexing or bending the neck. Ice packs for the first few days can help to reduce swelling and lower the risk of hematoma. Individuals continue taking antibiotics until the first stitches are removed, about five days after the procedure. The remaining sutures are removed seven to ten days later. Many people return to work and limited activities within two weeks of the procedure.

Risks

Candidates with other medical conditions should consult with their primary care physician before undergoing a face lift. Lung problems, **heart disease**, and certain other conditions can lead to a higher risk of complications. Persons who use medications that affect blood clotting (including female hormones, aspirin, and some non-aspirin **pain** relievers) should stop taking these medications prior to surgery to lower the risk of developing a hematoma, the most frequent complication of face lifts. Most hematomas form within 48 hours of surgery. The typical sign is pain or swelling affecting one side of the face but not the other.

Another potential risk is nerve damage, which can affect a person's ability to raise an eyebrow, distort the smile, or result in limited sensation in the earlobe. However, most nerve injuries will repair themselves within two to six months.

Results

Some swelling and bruising is normal following a face lift. However, there should be a noticeable improvement in the contour of the face and neck. Some fine wrinkling of the skin may be improved, but deep wrinkles are likely to require another cosmetic procedure to improve their appearance.

Morbidity and mortality rates

In general, mortality and morbidity rates for face lifts and similar facial cosmetic procedures are very low. Almost all cases of mortality following facial **cosmetic surgery** involve patients who were treated for facial disfigurement because they had been severely burned or attacked by animals. Moreover, many plastic surgeons do not consider morbidity and mortality rates to be as significant as other factors in evaluating the success of facial cosmetic procedures. One group of researchers at the University of Washington

WWW.BOOKBAZ.IR

KEY TERMS

Hematoma—A complication of surgery in which a collection of blood forms below the skin.

Rhytidectomy—Wrinkle excision. It is an older, alternative term for a face lift.

Twilight anesthesia—An intravenous mixture of sedatives and other medications that decrease a person's awareness of the procedure being performed.

maintains that "[t]he most important measures of outcome in facial cosmetic surgery are quality of life and patient satisfaction, in contrast to other, more objective measures such as complications or mortality rates."

Alternatives

Isometric exercises are recommended as nonsurgical alternatives to face lift procedures. Injections of Botox (botulinum toxin) have been used to achieve the same results as a face lift. Botulinum toxin is a compound produced by the spores and growing cells of the organism that causes **botulism**, *Clostridium botulinum*, which causes muscle **paralysis**. It was first used clinically in the 1960s to treat neurological disorders, but also proved to be effective in paralyzing the facial muscles that cause crow's feet and frown wrinkles. Botulinum toxin, or Botox, was approved by the U.S. Food and Drug Administration (FDA) in April 2002 as a treatment for facial lines and wrinkles. Botox treatments must be repeated in approximately six months.

Some plastic surgeons have used a procedure called fat rebalancing to achieve outcomes similar to a traditional face lift procedure. Fat rebalancing involves relocation of fatty tissue from distant sites on the body to the face.

Coherent ultrapulse carbon dioxide laser treatment is newer treatment alternative to traditional face lift procedures. It is similar to dermabrasion but with the use of a laser.

Face transplantation

Definition

Face transplantation is surgery to replace part or all of a patient's face with facial tissue from a deceased organ donor, resulting in a new or partially new face.

Purpose

Since the first human facial composite tissue allotransplantation (CTA) was performed in France in 2005, a number of additional partial or full face transplants have been attempted. As of 2014, all reported face transplants had been performed on patients for whom all other options had failed and for whom a face transplant represented the only possibility of regaining the ability to pursue usual activities of daily living and of enjoying a reasonable quality of life.

The first partial face **transplant surgery** in the United States was performed at the Cleveland Clinic in December of 2008. The recipient had lost most of the midsection of her face in 2004 after being shot by her husband. The third full face transplant, and the first full transplant in the United States, was performed in 2011 at Brigham and Women's Hospital in Boston. Virtually all of the young man's facial features had been burned off in 2008, following contact with a high-voltage wire during the painting of a Texas church from inside a cherry picker. Brigham and Women's Hospital subsequently performed a second full face transplant on a young man burned by a high-voltage wire following an automobile accident in 2001. The most extensive face transplant to date was performed in 2012, at the University of Maryland Medical Center. The recipient had lived as a recluse for 15 years, after half of his face was destroyed in a gunshot accident. By the time he was selected as a face transplant candidate in 2005, he had already undergone more than a dozen surgeries. Transplants had also been performed on patients with severely disfigured faces from **birth defects**, **trauma**, or cancer, for whom other treatment options had failed or could not be tolerated. Candidates awaiting face transplants included a woman who had been mauled by a chimpanzee.

Reports of early successful face transplants garnered a great deal of publicity. This raised concerns that some people might pursue a face transplant for cosmetic purposes or to swap their face for someone else's, as has sometimes been depicted in the movies. This prompted the American Academy of Facial Plastic and Reconstructive Surgery (AAFPRS) to issue a policy statement emphasizing that the surgery is an option only for carefully selected patients with facial deformities due to congenital malformations, cancer, or accidents—and only after all other treatment options have been exhausted. In particular, the AAFPRS stated that the procedure should be considered only for patients for whom trauma, **burns**, congenital deformity, or extensive facial tumors resulted in exposed brain tissue or threatened the eyes with permanent blindness. The AAFPRS affirmed that face transplants are not currently justifiable for skin and soft tissue restoration. However, the authors did suggest that in the future—after all medical, psychological, social, and ethical aspects of the treatment had been adequately evaluated in patients with the most severe conditions—face transplants might be considered for aesthetic restoration of conditions such as superficial burns in medically qualified patients.

KEY TERMS

Allograft—Allotransplantation; a transplant with donor tissue that is genetically different from that of the recipient.

Composite tissue allotransplantation (CTA)—Transplantation of a functional unit made up of different tissues, such as a hand or face.

Free flap facial surgery—Facial reconstruction using skin obtained from another part of the patient's body.

Immunosuppressive drugs—Medications that suppress the immune system to prevent rejection of a transplant.

Prophylaxis—Measures to prevent infection or other disease.

Thrombosis—The formation of a blood clot within a blood vessel.

Description

Face transplants are performed at only a very few advanced medical centers around the world. They have been reported to involve anywhere from about 15 to more than 150 surgeons, anesthesiologists, other specialists, nurses, and staff.

Face transplant requires procurement of healthy tissue from a compatible deceased donor. The donor tissue must be chosen and harvested with great precision. Once the tissue becomes available, the recipient is prepped for surgery. Any remaining injured or dead tissue is removed. The surgeons then attach the patient's nerves, muscles, and bony structures to the new face, reconnect each layer of the face, and restore blood flow. The actual techniques of the procedure utilize protocols that have been well established with organ and hand transplants; however, face transplants are even more complex and take more time. Harvesting of the donor face and implanting into the recipient have been reported to take anywhere from 15 to 36

WWW.BOOKBAZ.IR

hours. Face transplants will probably never become commonplace, not only because of the highly sophisticated surgery required, but also because of the associated risks and the numerous psychological and ethical issues. As with other transplant procedures, recipients of face transplants must take immunosuppressive medications for the rest of their lives. These medications can cause many side effects and shorten life expectancy.

Successful face transplants

Following long-term CTA survival in an animal model, the first human CTA was the successful transplantation of an immunologically compatible hand in Lyon, France, in 1998. This was followed by several more successful hand transplants and the first partial facial CTA in 2005. The new procedure was brought to the attention of the American public in 2008, with the announcement of the successful transplant of 80% of a female patient's face.

The first full face transplant, including all intact aesthetic and functional units, was reported in 2010 in Barcelona, Spain. The donor was a 41-year-old man who had died of a massive brain hemorrhage. The transplant recipient was a 30-year-old man with severe facial deformities from a 2005 ballistic trauma. The transplant included the forehead, nose, eyelids, cheeks, lips, and chin, all of the soft tissues, and a portion of the underlying bone. This was subsequently classified as a Type V facial allograft.

The first full face transplant in the United States included the patient's nose, lips, facial skin, muscles, and nerves required for facial animation. The first University of Maryland surgery involved a complete replacement from the patient's scalp to the midline of his neck, including jawbones, teeth, and part of the tongue, as well as muscles and nerves.

Preparation

Because face transplants are such new and complex surgeries and because there are so few compatible donors, facially damaged or deformed patients are treated with skin grafts or free facial flap surgeries if at all possible. Flap surgeries utilize the patient's own skin and tissue from elsewhere in the body to reconstruct the face, so there is no danger of rejection.

Before contemplating the possibility of a face transplant, all other methods of facial reconstruction must be considered, if not actually attempted. Some early transplant recipients had undergone more than 20 surgeries prior to their face transplant.

Extensive psychological assessment is required to ensure that the patient has the emotional health to endure the risks and **pain** of the surgery and the psychological uncertainties of life with a new face. In addition, due to the medical issues associated with immunosuppressive medications, there must be reassurance about compliance with medical care and follow-up. This preparatory period may take as long as three years.

Prior to surgery, the patient's immune system is suppressed with drugs to reduce the risk that the foreign tissue will be rejected. **Antiviral drugs** and **antibiotics** are administered as **prophylaxis** to help prevent infection.

Aftercare

Face transplantation requires a long period of hospitalization and a much longer and very complex **rehabilitation**. Patients may remain hospitalized for several months following the surgery, while inflammation is reduced and transplant rejection is prevented by very high doses of **immunosuppressant drugs**. Following discharge, patients must remain in the area for frequent examinations by the transplant team, as well as sessions with psychologists, social workers, and physical and speech therapists. Frequent physical examinations will probably be necessary for the remainder of the patient's life.

Face transplant recipients may require short-term mechanical ventilation for breathing assistance following the surgery, and additional soft-tissue surgeries are usually required as well. The recipients must learn to speak, eat, and produce facial expressions with their new face. The process of regaining facial muscle function and sensation can take many months. Regaining the ability to speak properly can take much longer. For patients who have not been able to eat or speak properly for many years, learning to use a new functional face, possibly including teeth and a tongue, is a major long-term challenge.

Risks

Morbidity and mortality rates for face transplants are not yet known. Although successful face transplants are being reported in the scientific and popular media, failures are less likely to be documented. There have been reports of fatalities in otherwise healthy patients who have undergone face transplants.

New transplant procedures for an organ or a large body part such as the face are extremely high-risk surgeries. Face transplants are not yet considered safe, particularly for patients who are not otherwise

medically stable. Mild bouts of transplant rejection, such as redness and swelling, are usually treatable, but transplant rejection will remain a lifelong risk. One case report of a full face transplant included various postoperative complications, including thrombosis (**blood clots**) and acute episodes of rejection, although these were treated and resolved. There remains a lifelong risk of tissue death or permanent loss of sensation or movement in the transplanted face.

New transplant procedures engender a great deal of media attention. Although some face transplant recipients have come forward or even courted media attention, the privacy of other recipients must be respected by everyone involved in the procedure.

Drugs

Transplant recipients require lifelong **immunosuppression** with very expensive drugs. These drugs leave patients vulnerable to a host of other diseases and conditions, in addition to generating huge medical bills. Dependence on immunosuppressive drugs increases the risk of infection, cancer, and organ failure. Although the lifelong risks of immunosuppression are common to all organ and tissue transplant patients, most transplants are performed for life-threatening conditions. In contrast, face transplants have thus far been performed on patients who are otherwise in good health.

Results

Thus far, the results of face transplantations—at least those that have been reported in the media and in medical journals—have been surprisingly good. The first face transplant in 2005 and the first full transplant in 2010 both restored the patients' appearance, facial function, and quality of life. Some patients have regained their ability to speak, chew, smell, and smile within as little as one year of the transplant. Other patients have been able to breathe freely for the first time in years. Patients have regained varying amounts of sensation in their transplanted faces. The regaining of facial sensation and function depends on whether the surgeons were able to connect the patient's major nerves to the nerves in the transplanted facial tissue. In some cases, extensive nerve damage from the original injuries makes such reconnections impossible. An assessment of four patients who had partial or full facial transplants between 2009 and 2011 found that some of them could breathe, eat, and talk easily one year after the surgery. These patients had also regained their sense of smell, could manage facial expressions, and were able to socialize to some degree. One full-facial transplant patient was discharged from the hospital after four months with near-complete facial sensation and partial motor recovery and without psychological complications. Nevertheless, although the long-term outcomes of face transplants are not yet known, there is an expectation that they will eventually require repair or replacement.

Transplanted faces look neither like the patient's original face before the injury nor like the donor's face. They may appear somewhat like a hybrid of the two. Furthermore, the psychological ramifications of having a new face are not yet known, since facial features are so central to personal identity and sense of self. The psychological impact of having a normal-appearing face after years of living hidden away from other people are also not well understood. Still, at least one transplant recipient reported that his new face felt natural and had become his own.

Margaret Alic, PhD

Factitious disorders

Definition

Factitious disorders are a group of mental disturbances in which patients intentionally act physically or mentally ill without obvious benefits. The name factitious comes from a Latin word that means artificial. These disorders are not **malingering**, which is defined as pretending illness when the "patient" has a clear motive, such as financial gain.

Description

Patients with factitious disorders produce or exaggerate the symptoms of a physical or mental illness by a variety of methods, including contaminating urine samples with blood, taking hallucinogens, injecting themselves with bacteria to produce infections, and other similar behaviors.

No reliable statistics on the frequency of factitious disorders are available, but factitious disorders are more common in men than in women. The following conditions are sometimes classified as factitious disorders:

Munchausen syndrome

Munchausen syndrome refers to patients whose factitious symptoms are dramatized and exaggerated. Many persons with Munchausen go so far as to undergo major surgery repeatedly, and, to avoid detection, at several locations. Many have been employed in hospitals or in healthcare professions. The syndrome's onset is in early adulthood.

Munchausen by proxy

Munchausen by proxy is the name given to factitious disorders in which a parent or other caregiver may but are falsify a child's medical history or tamper with laboratory tests in order to make the child appear sick. Occasionally, the parent may actually injure the child to assure that he or she will be treated.

Ganser's syndrome

Ganser's syndrome is an unusual dissociative reaction to extreme **stress** in which the patient gives absurd or silly answers to simple questions. It has sometimes been labeled as psychiatric malingering, but is more often classified as a factitious disorder.

Causes and symptoms

No single explanation of factitious disorders covers all cases. These disorders are variously attributed to underlying **personality disorders**; **child abuse**; the wish to repeat a satisfying childhood relationship with a doctor; and the desire to deceive or test authority figures. Also, the wish to assume the role of patient and receive care is involved. In many cases, the suffering of a major personal loss has been implicated.

The following are regarded as indications of a factitious disorder:

- dramatic but inconsistent medical history
- extensive knowledge of medicine and/or hospitals
- negative test results followed by further symptom development
- symptoms that occur only when the patient is not being observed
- few visitors
- arguments with hospital staff or similar acting-out behaviors
- eagerness to undergo operations and other procedures

When patients with factitious disorders are confronted, they usually deny that their symptoms are intentional. They may become angry and leave the hospital. In many cases they enter another hospital, which has led to the nickname "hospital hoboes."

KEY TERMS

Ganser's syndrome—An unusual factitious disorder characterized by dissociative symptoms and absurd answers to direct questions.

Malingering—Pretending to be sick in order to be relieved of an unwanted duty or obtain some other obvious benefit.

Munchausen by proxy—A factitious disorder in which a parent or other caregiver may falsify a child's medical history or take other action to make a healthy child appear sick.

Munchausen syndrome—A factitious disorder in which the patient's symptoms are dramatized and exaggerated.

Diagnosis

Diagnosis of factitious disorders is usually based on the exclusion of bona fide medical or psychiatric conditions, together with a combination of the signs listed earlier. In some cases, the diagnosis is made on the basis of records from other hospitals.

Treatment

Treatment of factitious disorders is usually limited to prompt recognition of the condition and the refusal to give unnecessary medications or to perform unneeded procedures. Individuals with factitious disorder do not usually remain in the hospital long enough for effective psychiatric treatment. Some clinicians have tried psychotherapeutic treatment for factitious disorder patients, and anecdotal reports suggest that antidepressant or antipsychotic medications are helpful in certain cases.

Prognosis

Some patients have only one or two episodes of factitious disorders; others develop a chronic form that may be lifelong. Successful treatment of the chronic form appears to be rare.

Failure to thrive

Definition

Failure to thrive (FTT) is used to describe a serious delay in a child's growth or development. This diagnosis usually is applied to infants and children up to two years of age who do not gain or maintain weight as they should. Failure to thrive is not a specific disease, but rather a cluster of symptoms that may come from a variety of sources.

Demographics

Premature infants are at greatest risk for failure to thrive. As many as 10% of hospitalized young children show some signs of failure to thrive. The rate of failure to thrive for non-specific physiological reasons (nonorganic failure to thrive) is higher in the United Sates than in other developed countries. Internationally, **malnutrition** is the most common cause of failure to thrive.

Description

Shortly after birth most infants lose some weight. After that expected loss, infants normally gain weight at a steady and predictable rate. When an infant does not gain weight as expected, or continues to lose weight, he or she is not thriving. Failure to thrive may be due to one or more conditions.

Organic failure to thrive (OFTT) implies that the organs involved with digestion and absorption of food are malformed or incomplete so the baby cannot digest its food. Nonorganic failure to thrive (NOFTT) is the most common cause of FTT and implies the baby is not receiving enough food due to economic factors, parental neglect, or psychosocial problems.

Causes and symptoms

Occasionally, underlying physical conditions inhibit an infant's ability to take in, digest, or process food. These defects can occur anywhere in the digestive tract—in the esophagus, stomach, small or large intestine, rectum, or anus. Usually the defect is an incomplete development of the organ, and it must be surgically corrected. Other physical causes of FTT

WWW.BOOKBAZ.IR

KEY TERMS

Esophagus—The muscular tube that leads from the back of the throat to the stomach. Coated with mucus and surrounded by muscles, it pushes food to the stomach by contraction.

Psychosocial—A term referring to the mind's ability, consciously or unconsciously, to adjust and relate the body to its social environment.

include hormonal abnormalities, chromosomal abnormalities, **cystic fibrosis**, and metabolic disorders. Most physical defects can be detected shortly after birth.

Failure to thrive may also result from lack of available food or the quality of the food offered. This can be due to economic factors in the family, parental beliefs and concepts of **nutrition**, or neglect of the child. In addition, if the infant is breastfed, the quality or quantity of the mother's milk may be the source of the problem.

Psychosocial problems, often stemming from lack of a nurturing parent-child relationship can lead to a failure to thrive. The child may exhibit poor appetite due to depression related to from insufficient attention from parents.

Infants and toddlers whose growth is substantially less than expected, are considered to be suffering from FTT.

Diagnosis

Infants are weighed at birth, and that weight is used as a baseline in future well-baby check-ups. If the infant is not gaining weight at a predictable rate, the doctor will do a more extensive examination. If no apparent physical deformities in the digestive tract exist, the doctor will examine the child's environment. As part of that examination, the doctor will look at the family history of height and weight. In addition, the parents will be asked about feedings, illnesses, and family routines. If the mother is **breastfeeding** the doctor will also evaluate her diet, general health, and well-being as it affects the quantity and quality of her milk.

Treatment

If the baby has an underlying physical reason for failure to thrive, such as a disorder of swallowing mechanism or intestinal problems, correcting that problem should reverse the condition. If the condition is caused by environmental factors, the physician will suggest several ways parents may provide adequate food for the child. Maternal education and parental counseling may also be recommended. In extreme cases, hospitalization or a more nurturing home may be necessary.

Prognosis

The first year of life is important as a foundation for growth and physical and intellectual development in the future. Children with extreme failure to thrive in the first year may never catch up to their peers, even if their physical growth improves. In about one-third of these extreme cases, mental development remains below normal and roughly half will continue to have psychosocial and eating problems throughout life.

When failure to thrive is identified and corrected early, most children catch up to their peers and remain healthy and well-developed.

Prevention

Initial failure to thrive caused by physical defects cannot be prevented but can often be corrected before they become a danger to the child. Maternal education and emotional and economic support systems all help to prevent failure to thrive in those cases where no physical deformity exists.

Dorothy Elinor Stonely
REVISED BY TISH DAVIDSON, AM

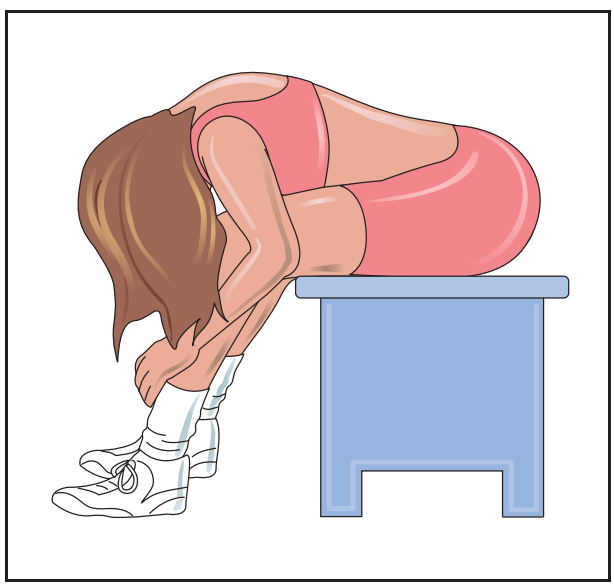
Fainting

Definition

Fainting, also called syncope, is a transient loss of consciousness and muscle control brought about by an inadequate amount of oxygen reaching the brain.

Demographics

Fainting is a common occurrence. About six people faint for the first time for every 1,000 patient years. Of these, about 3% will faint again. In people with **heart disease**, the rate of repeat fainting is about 10%.



If a person is feeling faint, unconsciousness may be prevented by sitting with the head between the knees, as shown in the illustration above, or by lying flat with the legs raised. *(Illustration by Electronic Illustrators Group. © Cengage Learning®.)*

The incidence of fainting is about the same worldwide; it appears to be unaffected by gender or ethnicity. However, the elderly are more likely to faint than younger people, and children rarely faint. One reason the elderly are more likely to faint is that fainting often is associated with heart disease, which is much more common in the elderly.

Description

A person who faints temporarily loses consciousness and muscle control. The period of unconsciousness lasts anywhere from a few seconds to a few minutes. Recovery is spontaneous. Fainting normally causes no permanent damage to the brain, although the individual may be injured by falling when losing muscle control.

Physicians distinguish several categories of fainting. Cardiac fainting (cardiac syncope) occurs because heart disease prevents the heart from pumping enough blood to the brain. A person with cardiac syncope tends to faint more than once. Cardiac syncope is a sign of a serious health problem. In a study by the New York Heart Association, 45% of individuals with heart disease and cardiac syncope died within one year compared to 12% of equally ill people who did not faint.

Reflex fainting occurs in response to events such as emotional **stress**, fear, or physical **pain**. Situational fainting occurs reproducibly when the individual assumes a certain posture or performs a specific act. For example, micturation syncope produces a feeling of lightheadedness immediately after urinating. Reflex and situational fainting are not life-threatening and rarely indicate the presence of serious disease.

Orthostatic hypotension occurs when a person rises from lying or sitting to standing. Changing position causes blood pressure to drop suddenly in some people, resulting in a feeling of lightheadedness or a brief faint. Orthostatic **hypotension** can be caused by certain drugs (both prescription and illicit), heavy alcohol consumption, some diseases (e.g., Parkinson's disease, **dementia**) and decreased blood volume (e.g., **dehydration**, severe blood loss).

Risk factors

Risk factors for fainting include heart disease, blood loss, dehydration, emotional distress, heavy use of alcohol, and use of illicit drugs or misuse of prescription drugs. Anemia may contribute to fainting, as may a drop in blood-sugar levels, especially in people with diabetes.

WWW.BOOKBAZ.IR

KEY TERMS

Cardiomyopathy—Disease of the heart muscle.

Patient years—The number of patients multiplied by the number of years that they were followed in a study divided by the number of study events that occurred (in this case, the number of fainting episodes of the group).

Parkinson's disease—A neurological disorder caused by deficiency of dopamine, a neurotransmitter, that assists in transmitting messages between the nerves within the brain. It is characterized by muscle tremor or palsy and rigid movements.

Causes and symptoms

Fainting is caused by inadequate amounts of oxygen reaching the brain. Cardiac syncope can be brought on by **vascular disease**, **congestive heart failure**, irregular heart rhythms (cardiac arrhythmia), heart valve disease, or disease of the heart muscle (**cardiomyopathy**). The causes of less serious types of fainting are based on emotional responses, changes in blood pressure, decreased blood volume, etc. In all cases, the individual feels lightheaded and briefly loses consciousness.

Diagnosis

The goal of diagnosis is to distinguish between fainting and a seizure or **stroke**, and to determine the cause for fainting.

Examination

During an examination, the physician assesses vital signs and takes a medical history, along with a detailed history of the event and circumstances under which fainting occurred. A drug history, including herbal and dietary supplements, is also be taken.

Tests

Depending on initial findings, the age of the individual, and the circumstances surrounding the fainting episode, extensive follow-up cardiac testing may be ordered to look for evidence of heart rhythm irregularities, congestive **heart failure**, heart valve damage, **heart murmurs**, and blockage of the blood vessels. Neurological tests may be performed.

Treatment

Treatment depends on the underlying cause of the fainting. In cases of reflex and situational fainting, no treatment may be needed. People experiencing orthostatic hypotension are counseled on how to move safely from lying or standing to prevent injury from fainting. People with cardiac fainting continue medical care, most likely supervised by a cardiologist.

Prognosis

People with reflex or situational fainting normally experience no lasting effects from fainting, although they may injure themselves from falling when losing consciousness. Injury is especially likely with the elderly who often break bones when falling.

Individuals who faint because they have heart disease are at increased risk for health problems including stroke and **heart attack**. The outcome of their situation depends on the severity of their heart disease and their response to treatment. Generally, cardiac syncope is a warning sign of serious heart problems that need ongoing medical care.

Prevention

Cardiac syncope is best prevented by following the advice of a cardiologist and taking heart medicine exactly as prescribed. Diabetics can help prevent fainting by monitoring and controlling their blood-sugar levels. Remaining well-hydrated, especially when playing sports or when ill with **diarrhea** and **vomiting**, also can help prevent lightheadedness and fainting.

Familial Mediterranean fever

Definition

Familial Mediterranean **fever** (FMF) is an inherited disorder of the inflammatory response characterized by recurring attacks of fever, accompanied by intense **pain** in the abdomen, chest, or joints. Attacks usually last 12–72 hours, and can occasionally involve a skin rash. **Kidney disease** is a serious concern if the disorder is not treated. FMF is most prevalent in people of Armenian, Sephardic-Jewish, Arabic, and Turkish ancestry.

Description

FMF could be described as a disorder of "inappropriate" inflammation. That is, an event that in a normal situation causes a mild or unnoticeable inflammation might cause a severe inflammatory response in someone with FMF. Certain areas of the body are at risk for FMF-related symptoms. A serosa is a serous (fluid-producing) membrane that can be found inside the abdominal cavity (peritoneum), around the lungs (pleura), around the heart (pericardium), and inside the joints (synovium). The symptoms of FMF are due to inflammation of one or more of the serosal membranes (serositis). Thus, FMF is also sometimes called recurrent polyserositis.

During an attack, large numbers of neutrophils, a type of white blood cell, move into the affected areas causing painful inflammation and fever. These episodes may be accompanied by a skin rash or joint pain. In a few cases, chronic arthritis is a problem. **Amyloidosis** is a potentially serious condition in which proteins called amyloids are mistakenly produced and deposited in organs and tissues throughout the body. Left untreated, amyloidosis often leads to kidney failure, which is the major long-term health risk in FMF.

In most cases, the attacks of fever and pain are first noticed in childhood or adolescence. The interval between these episodes may be days or months, and is not predictable. However, during these intervals people with FMF typically lead normal lives. It is not entirely clear what brings on an attack, but people with FMF often report mild physical **trauma**, physical exertion, or emotional **stress** just prior to the onset of symptoms. Treatment for FMF involves an oral medication called colchicine, which is highly effective for the episodes of fever and pain, as well as for amyloidosis and the kidney disease that can result from it.

Demographics

FMF is most common in certain ethnic groups from the eastern Mediterranean region, but cases in other ethnic groups in other parts of the world are increasingly being reported. FMF is also known by many other names. They include: recurrent hereditary polyserositis, benign paroxysmal **peritonitis**, familial paroxysmal polyserositis, paroxysmal polyserositis, familial recurrent polyserositis, periodic fever, periodic amyloid syndrome, periodic peritonitis syndrome, Reimann periodic disease, Reimann syndrome, Siegel-Cattan-Mamou syndrome, and Armenian syndrome.

Estimates of the incidence of FMF in specific eastern Mediterranean populations range from one in 2,000 to one in 100, depending on the population studied. Specific mutations in a gene—the MEFV gene—may cause a somewhat different course of the disease. Such mutations are more common in certain ethnic groups. A few mutations in the MEFV gene likely became common in a small population in the eastern Mediterranean several thousand years ago. It is postulated that carrying a single copy of a mutated gene produced a modified (but not abnormal) inflammatory response that may have been protective against some infectious agent at that time. Those who carried a single "beneficial" mutation in the MEFV gene were more likely to survive and reproduce, which may explain the high carrier frequency (up to one in five) in some populations. People of Armenian, Sephardic-Jewish, Arabic, and Turkish ancestry are at greatest risk for FMF. However, a better understanding and recognition of the symptoms of FMF in recent years has resulted in more reports of the condition in other ethnic groups, such as Italians and Armenian-Americans.

WWW.BOOKBAZ.IR

Causes and symptoms

FMF is a genetic condition inherited in an autosomal recessive fashion. Mutations in the MEFV gene (short for Mediterranean Fever) on chromosome number 16 are the underlying cause of FMF. Autosomal recessive inheritance implies that a person with FMF has mutations in both copies of the MEFV gene. All genes come in pairs, and one copy of each pair is inherited from each parent. If neither parent of a child with FMF has the condition, it means they carry one mutated copy of the MEFV gene, but also one normal copy, which is enough to protect them from disease. If both parents carry the same autosomal recessive gene, there is a one in four chance in each **pregnancy** that the child will inherit both recessive genes, and thus have the condition.

The MEFV gene carries the instructions for production of a protein called pyrin, named for pyrexia, a medical term for fever. The research group in France that co-discovered the protein named it marenostrin, after ancient Latin words that referred to the Mediterranean Sea. The movement of neutrophils into an area of the body where trauma or infection has occurred is the major cause of inflammation, which is a normal process. Research has shown that pyrin has some function in controlling neutrophils. In a situation where minor trauma or stress occurs, some initial inflammation may follow, but a functional pyrin protein is responsible for shutting down the response of neutrophils once they are no longer needed. An abnormal pyrin protein associated with FMF may be partly functional, but unstable. In some instances, the abnormal pyrin itself seems to be "stressed," and loses its ability to regulate neutrophils and inflammation. Left unregulated, a normal, mild inflammation spirals out of control. Exactly what causes pyrin in FMF to lose its ability to control neutrophils in some situations is not known.

The recurrent acute attacks of FMF typically begin in childhood or adolescence. Episodes of fever and painful inflammation usually last 12–72 hours. About 90% of people with FMF have their first attack by age 20. The group of symptoms that characterizes FMF includes the following:

Fever

An FMF attack is nearly always accompanied by a fever, but it may not be noticed in every case. Fevers are typically 100–104°F (38–40°C). Some people experience chills prior to the onset of fever.

Abdominal pain

Nearly all people with FMF experience abdominal pain at one point or another, and for most, it is the most common complaint. The pain can range from mild to severe, and can be diffuse or localized. It can mimic **appendicitis**, and many people with undiagnosed FMF have undergone appendectomies or exploratory surgery of the abdomen, only to have the fever and abdominal pain return.

Chest pain

Pleuritis, also called **pleurisy**, occurs in up to half of the affected individuals in certain ethnic groups. The pain is usually on one side of the chest. **Pericarditis** would also be felt as chest pain.

Joint pain

About 50% of people with FMF experience joint pain during attacks. The pain is usually confined to one joint at a time, and often involves the hip, knee, or ankle. For some people, however, the recurrent joint pain becomes chronic arthritis.

Myalgia

Up to 20% of individuals report muscle pain. These episodes typically last less than two days, and tend to occur in the evening or after physical exertion. Rare cases of muscle pain and fever lasting up to one month have been reported.

Skin rash

A rash, described as erysipelas-like erythema, accompanies attacks in a minority of people, and most often occurs on the front of the lower leg or top of the foot. The rash appears as a red, warm, swollen area about 4–6 in (10–15 cm) in diameter.

Amyloidosis

FMF is associated with high levels in the blood of a protein called serum amyloid A (SAA). Over time, excess SAA tends to be deposited in tissues and organs throughout the body. The presence and deposition of excess SAA is known as amyloidosis. Amyloidosis may affect the gastrointestinal tract, liver, spleen, heart, and testes, but effects on the kidneys are of greatest concern. The frequency of amyloidosis varies among the different ethnic groups, and its overall incidence is difficult to determine because of the use of colchicine to avert the problem. Left untreated, however, those individuals who do develop amyloidosis of the kidneys may require a renal transplant, or may even die of renal failure. The frequency and

KEY TERMS

Acute phase reactants—Blood proteins whose concentrations increase or decrease in reaction to the inflammation process.

Amyloid—A waxy translucent substance composed mostly of protein, that forms plaques (abnormal deposits) in the brain.

Amyloidosis—Accumulation of amyloid deposits in various organs and tissues in the body such that normal functioning of an organ is compromised.

Colchicine—A compound that blocks the assembly of microtubules–protein fibers necessary for cell division and some kinds of cell movements, including neutrophil migration. Side effects may include diarrhea, abdominal bloating, and gas.

Leukocyte—A white blood cell. The neutrophils are a type of leukocyte.

Leukocytosis—An increase in the number of leukocytes in the blood.

Neutrophil—The primary type of white blood cell involved in inflammation. Neutrophils are a type of granulocyte, also known as a polymorphonuclear leukocyte.

Pericarditis—Inflammation of the pericardium, the membrane surrounding the heart.

Peritonitis—Inflammation of the peritoneum, the membrane surrounding the abdominal contents.

Pleuritis—Inflammation of the pleura, the membrane surrounding the lungs.

Pyrexia—A medical term denoting fevers.

Serositis—Inflammation of a serosal membrane. Polyserositis refers to the inflammation of two or more serosal membranes.

Synovitis—Inflammation of the synovium, a membrane found inside joints.

severity of a person's attacks of fever and serositis seem to have no relation to whether they will develop amyloidosis. In fact, a few people with FMF have been described who have had amyloidosis but apparently no other FMF-related symptoms.

Other symptoms

A small percentage of boys with FMF develop painful inflammation around the testes. Headaches are a common occurrence during attacks, and certain types of **vasculitis** (inflammation of the blood vessels) seem to be more common in FMF.

Diagnosis

Individually, the symptoms that define FMF are common. Fevers occur for many reasons, and nonspecific pains in the abdomen, chest, and joints are also frequent ailments. Several infections can result in symptoms similar to FMF (Mallaret **meningitis**, for instance), and many people with FMF undergo exploratory abdominal surgery and ineffective treatments before they are finally diagnosed. Membership in a less commonly affected ethnic group may delay or hinder the correct diagnosis.

In general, symptoms involving one or more of the following broad groups should lead to suspicion of FMF: Unexplained recurrent fevers, polyserositis, skin rash, and/or joint pain; abnormal blood studies; and renal or other disease associated with amyloidosis. A family history of FMF or its symptoms would obviously be an important clue, but the recessive nature of FMF means patients usually have no family history. The diagnosis may be confirmed when a person with unexplained fever and pain responds to treatment with colchicine, since colchicine is not known to have a beneficial effect on any other condition similar to FMF. Abnormal results on a blood test typically include **leukocytosis** (elevated number of neutrophils in the blood), an increased **erythrocyte sedimentation rate** (rate at which red blood cells form a sediment in a blood sample), and increased levels of proteins associated with inflammation (called acute phase reactants) such as SAA.

Direct analysis of the MEFV gene for FMF mutations is the only method to be certain of the diagnosis. However, it is not yet possible to detect all MEFV gene mutations that might cause FMF. Thus, if DNA analysis is negative, clinical methods must be relied upon. If both members of a couple were proven to be FMF carriers through **genetic testing**, highly accurate prenatal diagnosis would be available in any subsequent pregnancy.

Similar syndromes of periodic fever and inflammation include familial Hibernian fever and hyperimmunoglobulinemia D syndrome, but both are more rare than FMF.

WWW.BOOKBAZ.IR

Treatment

Colchicine is a chemical compound that can be used as a medication, and is frequently prescribed for **gout**. Some years ago, colchicine was discovered to also be effective in reducing the frequency and severity of attacks in FMF. Treatment for FMF at this point consists of taking colchicine daily. Studies have shown that about 75% of FMF patients achieve complete remission of their symptoms, and about 95% show marked improvement when taking colchicine. Lower effectiveness has been reported, but there is some question about the number of FMF patients who choose not to take their colchicine between attacks when they are feeling well, and thus lose some of the ability to prevent attacks. Compliance with taking colchicine every day may be hampered by its side effects, which include **diarrhea**, nausea, abdominal bloating, and gas. There is a theoretical risk that colchicine use could damage chromosomes in sperms and eggs, or in an embryo during pregnancy, or that it might reduce fertility. However, studies looking at reproduction in men and women who have used colchicine have so far not shown any increased risks. Colchicine is also effective in preventing, delaying, or reversing renal disease associated with amyloidosis.

Other medications may be used as needed to deal with the pain and fever associated with FMF attacks. Dialysis and/or renal transplant might become necessary in someone with advanced kidney disease. Given its genetic nature, there is no cure for FMF, nor is there likely to be in the near future. Any couple that has a child diagnosed with FMF, or anyone with a family history of the condition (especially those in high-risk ethnic groups), should be offered **genetic counseling** to obtain the most up-to-date information on FMF and testing options.

Prognosis

For those individuals who are diagnosed early enough and take colchicine consistently, the prognosis is excellent. Most will have very few, if any, attacks of fever and polyserositis, and will likely not develop serious complications of amyloidosis. The problem of misdiagnosing FMF continues, but education attempts directed at both the public and medical care providers should improve the situation. Future research should provide a better understanding of the inflammation process, focusing on how neutrophils are genetically regulated. That information could then be used to develop treatments for FMF with fewer side effects, and might also assist in developing therapies for other diseases in which abnormal inflammation and immune response are a problem.

Scott J. Polzin, MS

Familial polyposis

Definition

Familial polyposis is an inherited condition that primarily affects the large intestine (colon and rectum). Large numbers of projecting masses of swollen and thickened or tumorous membrane (polyps) develop on the inner lining of this part of the bowel. The polyps eventually become malignant.

Demographics

Familial polyposis is a rare disease. Estimates of incidence of the disease vary from one in 7,000 to one in every 31,000 people in the United States. However, it may be very common in affected families. Familial polyposis is inherited in an autosomal dominant pattern. This means that a person with Familial polyposis has a 50% chance of passing the condition down to each of their children. Familial polyposis can also develop in someone with no family history of the disorder due to a new genetic mutation in that individual. It is thought that approximately 1% of all colorectal cancers in the United States can be attributed to Familial polyposis.

Description

Familial polyposis is known by many synonyms, most include some combination of words that reflect what is known about the disease. As the disease is inherited, the word "family" is often included. Because these mushroom-like growths are the most obvious manifestation of the disorder, the word "polyp" is usually in the term as well. Adenoma is frequently included and refers to the particular kind of polyp

that is typically discovered. Some of the names found in medical texts and journals include polyposis coli, familial colonic polyposis, multiple familial polyposis, familial adenomatous colon polyposis, adenomatosis of the colon and rectum (ACR), and familial adenomatous polyposis (FAP). The last term and its abbreviation have been commonly used since the early 1990s.

Familial polyposis or familial adenomatous polyposis is a premalignant disease. This means that a person with FAP, if left untreated, will invariably develop cancer. Individuals with this disorder grow hundreds to thousands of polyps throughout their large intestines. The polyps, which may also be called adenomas, commonly develop just after **puberty**. Approximately half of all FAP patients have polyps by age 16. About 90% have detectable polyps by age 25. Usually by age 35–40, one or more of these polyps becomes cancerous. The average age at which patients with FAP tend to develop **colon cancer** is 39 years.

Risk factors

Relatives of individuals with diagnosed FAP are at high risk of having the disease themselves. This condition has no other known risk factors.

Causes and symptoms

FAP is caused by a germline (inherited) mutation in the adenomatous polyposis coli (APC) gene. APC is a tumor suppressor gene, although its exact function is not yet completely understood. Researchers theorize that the normal gene directs the manufacture of a protein that helps control cell growth. The mutated gene section in FAP generates an abnormal protein that does not perform its normal function. Cells grow out of control, causing the development of multiple, sometimes hundreds or thousands of polyps. One or more of these eventually becomes cancerous.

Many individuals develop polyps without displaying any symptoms. Others experience such gastrointestinal problems as **diarrhea**, **constipation**, abdominal cramps, blood in the stool, or weight loss. FAP patients may also develop nonmalignant tumors (desmoid tumors), and/or some bone and dental abnormalities. In addition, they may exhibit a spot on the retina of the eye (congenital hypertrophy of the retinal pigment epithelium, or CHRPE). These eye changes often precede the development of polyposis.

KEY TERMS

Gene—The basic unit of heredity, made of DNA. Each gene occupies a certain location on a chromosome.

Mutation—An alteration in a gene, especially one capable of producing a new trait, or a change in function.

Diagnosis

Tests

The abnormal portion of the gene that causes FAP in most patients can be detected. A blood test can then be performed to identify family members who have the same mutation and who will eventually develop the condition. Children who have a parent with FAP, and siblings of affected patients whose parental history is incomplete, should be evaluated. The polyps characteristic of FAP have been found in children as young as age five. Testing of appropriate individuals should take place as soon as the diagnosis of FAP is established in one member of a family.

Relatives of people with diagnosed FAP should **exercise** caution regarding where they seek advice and testing. One study of a commercially available blood test found that less than 20% of patients received any **genetic counseling**, and almost one-third of their physicians misinterpreted the test results.

Registries for FAP patients can be found at many sites in the United States. Such a registry specializes in identification, assistance, and education of people with a particular disease, and is usually a separate department in a research hospital. A team of health professionals who have expertise in the disorder staff the registry.

Testing within a research setting and/or at a facility with a registry of patients with FAP is more likely to safeguard against problems, such as the misunderstanding of test results. Patients who participate in a research project sometimes receive counseling, as well as blood tests, at no charge. Insurance coverage varies. Concerns about confidentiality and future insurance and employment discrimination may prompt individuals to pay for the examination out-of- pocket.

Procedures

If the abnormal gene is found in a family member, annual screening for colon polyps is recommended

WWW.BOOKBAZ.IR

beginning at age 10 to 12 years. Flexible **sigmoidoscopy** is used for this examination. It is usually done in a physician's office, or in a hospital department, most often by a gastroenterologist or a surgeon. Food intake may be restricted for 24 hours prior to the procedure. Before the study, the intestine is cleared of stool by one or more small **enemas**. Some physicians prefer to sedate the patient to help them relax. A flexible, lighted, hollow tube (sigmoidoscope) is inserted into the anus and maneuvered into the large intestine. The physician examines the wall of the colon to look for polyps. If polyps are found, one or more may be removed for biopsy.

Most patients report little discomfort during the examination. The procedure itself takes five to 15 minutes. The patient may be at the facility an hour or more if recovery from **sedation** is needed. If no medication was administered, driving and resumption of normal activities are permitted immediately.

If the diagnosis of FAP is confirmed by sigmoidoscopy or **colonoscopy**, a front- and side-viewing **esophagogastroduodenoscopy** (EGD) procedure is strongly recommended. This procedure helps to determine if adenomas are present in other areas of the gastrointestinal tract such as the stomach and duodenum (small intestine). The second most common site for cancer development other than in the colorectal area in patients with FAP is the duodenum. This test is recommended every one to three years for individuals diagnosed with FAP.

Other screening tests that may be recommended include ultrasounds or CT scans to determine the presence of desmoid tumors in the abdominal area and to check for the development of pancreatic cancer. **Ultrasound** of the thyroid may be ordered because of the increased risk for **thyroid cancer** in patients with FAP.

In some cases, the portion of the gene responsible for FAP cannot be identified. Family members of these patients cannot have a predictive blood test. The current recommendation for these patients is the same as that for patients with a diagnosed FAP gene: to undergo to an annual examination with flexible sigmoidoscopy. A noninvasive screening **eye examination** to detect CHRPE, associated with FAP, may also be performed.

Treatment

The only definitive treatment for FAP is surgical removal of the lower intestine. In very young people, surgical removal of the colon (colectomy) may be delayed until the late teens or early 20s when most patients would be considered psychologically ready for such a procedure. However, surgery may be done at an earlier age if it is determined that the polyps are at an advanced histologic stage.

Several surgical choices are available to treat this condition. Some authorities advocate removal of the colon, leaving the rectum or lowest portion of the intestine in place. The small intestine can be attached to the rectum, allowing normal bowel function. This is often called ileorectal anastomosis. Others argue that this section is also liable to develop polyps, needs to be monitored regularly, and may require eventual removal.

Excision of the entire lower intestine with preservation of normal bowel function is possible. This entails a more complex surgical procedure. The patient may experience more complications and a longer recovery period. However, the risk of polyp development in this area is very low. Periodic examination of the intestine may not be needed once healing is complete.

The more intricate surgery may be referred to as a J-pouch procedure, an ileal pouch-anal anastomosis, a restorative proctocolectomy, or an ileoanal reservoir procedure. It involves creating a "pouch" of tissue from the small intestine, which is attached to the anus. This serves as a reservoir or holding area for stool, much as the rectum does normally. The surgery is often done in several stages. A temporary ileostomy, which creates an opening of the small intestine onto the abdomen, is required. When all procedures are completed, and after a recuperation period, the patient regains normal bowel function through the anus.

Some researchers suggest that as **genetic testing** becomes more developed, the specific portion of the gene involved may dictate the type of surgery chosen. Those at high risk of developing **rectal polyps** may be advised to have the more complex operation. FAP patients considered to be at lower risk for rectal polyps might be counseled to consider the less radical surgery.

Drugs

Medical therapy to treat the adenomatous polyps has been attempted. Some **nonsteroidal anti-inflammatory drugs** have been effective in reducing the number and size of the polyps in colorectal tissue that remains after surgery such as in an ileoanal anastomosis.

Individuals with FAP are at increased risk for cancers of the upper digestive tract including the upper

portion of the small bowel (duodenum) and the channels where bile flows (biliary tract). Cancers of the thyroid, pancreas, and adrenal gland are also more commonly found among FAP patients. Periodic examination for the development of malignancy in these areas is considered part of the treatment of FAP. In some cases, such as cancer involving the duodenum, the tests themselves carry a chance of complications. The risk of the study must be weighed against the potential benefits of knowing the results. Desmoid tumors also occur more frequently in patients with FAP. Although they are not malignant, they grow quickly into surrounding tissues, causing many difficulties, even death in some cases.

Prognosis

The major cause of death in many patients with FAP remains colorectal cancer. One study suggested that even with improved disease recognition, social and emotional factors, such as fear of surgery, may significantly delay a patient's treatment.

In patients who have undergone colectomy, desmoid tumors and cancers of the upper gastrointestinal tract are the leading causes of death. Medical surveillance is critical for patients with FAP even after surgical removal of the colon.

Prevention

FAP cannot be prevented. Aggressive diagnosis, treatment, and follow-up monitoring are keys to successful management of the disease.

Family therapy

Definition

Family therapy is a form of **psychotherapy** that involves all the members of a nuclear or extended family. It may be conducted by a pair or team of therapists. In many cases the team consists of a man and a woman in order to treat gender-related issues or serve as role models for family members. Although some forms of family therapy are based on behavioral or psychodynamic principles, the most widespread form is based on family systems theory. This approach regards the family as a whole, as the unit of treatment, and emphasizes such factors as relationships and communication patterns rather than traits or symptoms in individual members.

Family therapy is a relatively recent development in psychotherapy. It began shortly after World War II, when doctors, who were treating schizophrenic patients, noticed that the patients' families communicated in disturbed ways. The doctors also found that the patients' symptoms rose or fell according to the level of tension between their parents. These observations led to considering a family as an organism or system with its own internal rules, patterns of functioning, and tendency to resist change. The therapists started to treat the families of schizophrenic patients as whole units rather than focusing on the hospitalized member. They found that in many cases the family member with **schizophrenia** improved when the "patient" was the family system. (This should not be misunderstood to mean that schizophrenia is caused by family problems, although family problems may worsen the condition.) This approach of involving the entire family in the treatment plan and therapy was then applied to families with problems other than the presence of schizophrenia.

WWW.BOOKBAZ.IR

Family therapy is becoming an increasingly common form of treatment as changes in American society are reflected in family structures. It has led to two further developments: couple's therapy, which treats relationship problems between marriage partners or gay couples; and the extension of family therapy to religious communities or other groups that resemble families.

Purpose

Family therapy is often recommended in the following situations:

- Treatment of a family member with schizophrenia or multiple personality disorder (MPD). Family therapy helps other family members understand their relative's disorder and adjust to the psychological changes that may be occurring in the relative.
- Families with problems across generational boundaries. These would include problems caused by parents sharing housing with grandparents, or children being reared by grandparents.
- Families that deviate from social norms (common-law relationships, gay couples rearing children, etc.). These families may not have internal problems but may be troubled by outsiders' judgmental attitudes.
- Families with members from a mixture of racial, cultural, or religious backgrounds.
- Families who are scapegoating a member or undermining the treatment of a member in individual therapy.
- Families where the identified patient's problems seem inextricably tied to problems with other family members.
- Blended families with adjustment difficulties.

Most family therapists presuppose an average level of intelligence and education on the part of adult members of the family.

Precautions

Some families are not considered suitable candidates for family therapy. They include:

- families in which one, or both, of the parents is psychotic or has been diagnosed with antisocial or paranoid personality disorder
- families whose cultural or religious values are opposed to, or suspicious of, psychotherapy
- families with members who cannot participate in treatment sessions because of physical illness or similar limitations
- families with members who have very rigid personality structures. (Here, members might be at risk for an emotional or psychological crisis)
- families whose members cannot or will not be able to meet regularly for treatment
- families that are unstable or on the verge of breakup

Description

Family therapy tends to be short-term treatment, usually several months in length, with a focus on resolving specific problems such as **eating disorders**, difficulties with school, or adjustments to **bereavement** or geographical relocation. It is not normally used for long-term or intensive restructuring of severely dysfunctional families.

In family-therapy sessions, all members of the family and all therapists (families may have more than one) are present at most sessions. The therapists seek to analyze the process of family interaction and communication as a whole; they do not take sides with specific members. They may make occasional comments or remarks intended to help family members become more conscious of patterns or structures that had been previously taken for granted. Family therapists, who work as a team, also model new behaviors for the family through their interactions with each other during sessions.

Family therapy is based on family-systems theory, which understands the family to be a living organism that is more than the sum of its individual members. Family therapy uses systems theory to evaluate family members in terms of their position or role within the system as a whole. Problems are treated by changing the way the system works rather than trying to "fix" a specific member. Family systems theory is based on several major concepts:

The identified patient

The identified patient (IP) is the family member with the symptom that has brought the family into treatment. The concept of the IP is used by family therapists to keep the family from scapegoating the IP or using him or her as a way of avoiding problems in the rest of the system.

Homeostasis (balance)

The concept of homeostasis means that the family system seeks to maintain its customary organization and functioning over time. It tends to resist change. The family therapist can use the concept of homeostasis to explain why a certain family symptom has surfaced at a given time, why a specific member has

become the IP, and what is likely to happen when the family begins to change.

The extended family field

The extended family field refers to the nuclear family, plus the network of grandparents and other members of the extended family. This concept is used to explain the intergenerational transmission of attitudes, problems, behaviors, and other issues.

Differentiation

Differentiation refers to the ability of each family member to maintain his or her own sense of self, while remaining emotionally connected to the family. One mark of a healthy family is its capacity to allow members to differentiate, while family members still feel that they are "members in good standing" of the family.

Triangular relationships

Family systems theory maintains that emotional relationships in families are usually triangular. Whenever any two persons in the family system have problems with each other, they will "triangle in" a third member as a way of stabilizing their own relationship. The triangles in a family system usually interlock in a way that maintains family homeostasis. Common family triangles include a child and his or her parents; two children and one parent; a parent, a child, and a grandparent; three siblings; or a husband, wife, and an in-law.

Family therapy can be and is usually provided by clinical social workers or licensed therapists known as marriage and family therapists. Many of these therapists have postgraduate degrees and often become credentialed by the American Association for Marriage and Family Therapy (AAMFT).

KEY TERMS

Blended family—A family formed by the remarriage of a divorced or widowed parent. It includes the new husband and wife, plus some or all of their children from previous marriages.

Differentiation—The ability to retain one's identity within a family system while maintaining emotional connections with the other members.

Extended family field—A person's family of origin plus grandparents, in-laws, and other relatives.

Family-systems theory—An approach to treatment that emphasizes the interdependency of family members rather than focusing on individuals in isolation from the family. This theory underlies the most influential forms of contemporary family therapy.

Genogram—A family tree diagram that represents the names, birth order, sex, and relationships of the members of a family. Therapists use genograms to detect recurrent patterns in the family history and to help the members understand their problem(s).

Homeostasis—The tendency of a family system to maintain internal stability and resist change.

Identified patient (IP)—The family member in whom the family's symptom has emerged or is most obvious.

Nuclear family—The basic family unit, consisting of father, mother, and their biological children.

Triangling—A process in which two family members lower the tension level between them by drawing in a third member.

Preparation

In some instances, a pediatrician or other primary care provider may have referred the family to a specialist in family therapy. It is estimated that as many as 50 percent of office visits to pediatricians have to do with children's developmental problems that are affecting their families. Some family doctors use symptom checklists or psychological screeners to assess a family's need for therapy.

Family therapists may be either psychiatrists, clinical psychologists, or other professionals certified by a specialty board in marriage and family therapy. They will usually evaluate a family for treatment by scheduling a series of interviews with the members of the immediate family, including young children, and significant or symptomatic members of the extended family. This process allows the therapist(s) to find out how each member of the family sees the problem, as well as to form first impressions of the family's functioning. Family therapists typically look for the level and types of emotions expressed, patterns of dominance and submission, the roles played by family members, communication styles, and the locations of emotional triangles. They will also note whether these patterns are rigid or relatively flexible.

Preparation also usually includes drawing a genogram, which is a diagram that depicts significant persons and events in the family's history. Genograms also include annotations about the medical history and major personality traits of each member.

WWW.BOOKBAZ.IR

Genograms help in uncovering intergenerational patterns of behavior, marriage choices, family alliances and conflicts, the existence of family secrets, and other information that sheds light on the family's present situation.

Risks

The chief risk in family therapy is the possible unsettling of rigid personality defenses in individuals, or couple relationships that had been fragile before the beginning of therapy. Intensive family therapy may also be difficult for psychotic family members.

Results

Normal results vary, but in good circumstances, they include greater insight, increased differentiation of individual family members, improved communication within the family, loosening of previously automatic behavior patterns, and resolution of the problem that led the family to seek treatment.

Famine fever *see* **Relapsing fever**

Fanconi's syndrome

Definition

Fanconi's syndrome is a set of kidney malfunctions brought about by a variety of seemingly unrelated disorders. Kidney malfunction leads to excessive urine production and excessive thirst, resulting in deficits of water, **calcium**, potassium, magnesium, and other substances in the body. It often leads to bone disease and stunted growth.

Description

Normally, kidneys cleanse the blood and keep its salt, water, and acidity in balance, leaving what the body needs in the blood and putting what the body doesn't need into the urine, which leaves the body. This task is performed in two steps. First, the blood is filtered through a kidney structure with small holes that keep the cells and large molecules in the blood. Second, some of the small molecules in the filtrate, needed by the body, are reabsorbed and returned to the bloodstream.

This reabsorption step is defective in Fanconi's syndrome. As a consequence, substances that are normally reabsorbed, such as glucose, amino acids, small proteins, water, calcium, potassium, magnesium, bicarbonate, and phosphate, are lost and the body becomes overly acidic.

Demographics

Fanconi's syndrome is also known as Fanconi syndrome, renal Fanconi syndrome, Fanconi renaltubular syndrome, and Lignac-de Toni-Debré-Fanconi syndrome. Fanconi's anemia, however, is a totally different disease.

Causes and symptoms

Causes

Fanconi's syndrome can be caused by a variety of genetic defects and by certain environmental assaults.

The genetic diseases known to give rise to Fanconi's syndrome are cystinosis (the most common cause in children), **galactosemia**, glycogen storage disease, **hereditary fructose intolerance**, Lowe syndrome, **Wilson disease**, tyrosinemia, medullary cystic disease, **vitamin D** dependency, and familial idiopathic Fanconi's syndrome.

Environmental assaults that cause Fanconi's syndrome include exposure to heavy metals (like cadmium, lead, mercury, platinum, uranium), certain drugs (like outdated tetracycline and gentamicin), other substances (like Lysol, paraquat, toluene, the amino acid lysine taken as a nutritional supplement), and **kidney transplantation**.

KEY TERMS

Acidosis—Condition where the body is more acidic than normal; associated with headache, nausea, vomiting, and visual disturbances.

Fanconi's anemia—An inherited form of aplastic anemia.

Filtrate—The part of filtered material that flows through the filter.

Idiopathic—Refers to a disease of unknown cause.

Polydipsia—Excessive thirst.

Polyuria—Excessive production of urine.

Symptoms

Fanconi's syndrome symptoms related directly to impaired absorption include excessive urine production and urination; excessive thirst; **dehydration**; **constipation**; **anorexia nervosa**; **vomiting**; elevated levels of glucose, phosphate, calcium, uric acid, amino acids, and protein (especially beta$_2$-microglobulin and lysozyme) in the urine; elevated levels of chloride and decreased levels of phosphate and calcium in the blood; and excessively acidic blood.

The most noticeable indirect consequences of impaired reabsorption are two bone diseases: **rickets** and osteomalacia. Rickets affects children and is associated with bone deformities, failure to grow, and difficulty walking. If a person acquires Fanconi's syndrome as an adult, the bone disease is termed osteomalacia and is accompanied by severe bone **pain** and spontaneous **fractures**. Unlike rickets due to **malnutrition**, these diseases cannot be reversed with vitamin D. Muscle weakness and occasional **paralysis** are other indirect consequences of the ineffective reabsorption.

Diagnosis

Diagnosis of Fanconi's syndrome can be made by urine and blood tests. It is also important to find the underlying cause to decide on the best treatment. Other symptoms specific to a particular patient will point to other useful diagnostic tests. For example, high levels of blood galactose in conjunction with symptoms of Fanconi's syndrome indicate the patient is suffering from galactosemia, while high blood levels of cadmium indicate the patient is suffering from cadmium **poisoning**.

Treatment

Fanconi's syndrome is best treated by attacking the underlying cause whenever possible. For example, when cystinosis is treated with the drug cysteamine to lower cystine levels in the body or Wilson disease is treated with penicillamine to lower the levels of copper, accompanying symptoms of Fanconi's syndrome will subside. If the patient has acquired the disease from a heavy metal or another toxic agent, all contact with the toxic agent should stop; the condition will then likely disappear.

Nevertheless, additional treatment will be necessary either when it's not possible to treat the underlying cause or while waiting for the kidneys to resume normal function. This is done by restricting **sodium** chloride (table salt), giving **antacids** to counteract the excessive acidity of the blood, and supplying potassium supplements.

Kidney transplant is the treatment of last resort, used for patients whose kidneys have failed.

Prognosis

Fanconi's syndrome can be reversible. When caused by kidney transplantation it usually reverses itself within the first year after **transplant surgery**. When caused by a toxin in the environment, Fanconi's syndrome generally can be reversed by removing the causative agent from the patient's environment. If it is caused by a genetic disease, it can usually be reversed by treating the disease. However, if Fanconi's syndrome is not treated or if treatment is unsuccessful, the kidneys can fail.

Prevention

Fanconi's syndrome caused secondarily by the genetic diseases galactosemia, glycogen-storage disease, hereditary fructose intolerance, and tyrosinemia is prevented by appropriate dietary restrictions to treat the genetic disease, starting in infancy.

Fanconi's syndrome caused by heavy metals and other toxins can be prevented by avoiding these substances.

Fasciotomy

Definition

Fasciotomy is a surgical procedure that cuts away the fascia to relieve tension or pressure.

Purpose

The fascia is thin connective tissue covering, or separating, the muscles and internal organs of the body. It varies in thickness, density, elasticity, and composition, and is different from ligaments and tendons.

The fascia can be injured either through constant strain or through **trauma**. Fasciitis is an inflammation of the fascia. The most common condition for which fasciotomy is performed is plantar fasciitis, an inflammation of the fascia on the bottom of the foot that is sometimes called a heel spur or stone bruise.

Plantar fasciitis is caused by long periods on the feet, being overweight, and wearing shoes that do not support the foot well. Teachers, mail carriers, runners, and others who make heavy use of their feet are especially likely to suffer from plantar fasciitis.

Plantar fasciitis results in moderate to disabling heel **pain**. If nine to 12 months of conservative treatment (reducing time on feet, non steroidal anti-inflam matory drugs, arch supports) under the supervision of a doctor does not result in pain relief, a fasciotomy may be done. Fasciotomy removes a small portion of the fascia to relieve tension and pain. Connective tissue grows back into the cut space left by the cut, effectively lengthening the fascia.

When a fasciotomy is performed on other parts of the body, it is usually done to relieve pressure from a compression injury to a limb. This type of injury often occurs during contact sports. The blood vessels of the limb are damaged. They swell and leak, causing inflammation. Fluid builds up in the area contained by the fascia. A fasciotomy is done to relieve this pressure and prevent tissue death. Similar injury occurs in high voltage electrical **burns** where deep tissue damage occurs.

Precautions

In the case of injury, fasciotomy is done on an emergency basis, and the outcome of the surgery depends largely on the general health of the patient. Plantar fasciotomies are appropriate for most people whose foot problems cannot be resolved in any other way.

Description

Fasciotomy in the limbs is usually done by a surgeon under general or regional **anesthesia**. An incision is made in the skin, and a small area of fascia is removed where it will best relieve pressure. Then the incision is closed.

Plantar fasciotomy is an endoscopic (performed with the use of an endoscope) procedure. It is done by a foot specialist in a doctor's office or outpatient surgical clinic under local anesthesia and takes 20 minutes to one hour. The doctor makes two small incisions on either side of the heel. An endoscope is inserted in one to guide the doctor in identifying the location to make the cut. A tiny knife is inserted in the other. A portion of the fascia is cut from near the heel, after which then the incisions are closed.

Preparation

Little preparation is done before a fasciotomy. When the fasciotomy is related to burn injuries, the fluid and electrolyte status of the patient are constantly monitored.

Aftercare

Aftercare depends on the reason for the fasciotomy. People who have endoscopic plantar fasciotomy can walk without pain almost immediately, return to wearing their regular shoes within three to five days, and return to normal activities within three weeks. Most will need to wear arch supports in their shoes.

Risks

In endoscopic plantar fasciotomy, the greatest risk is that the arch will drop slightly as a result of this surgery, causing other foot problems. Risks involved with other types of fasciotomy are those associated with

KEY TERMS

Endoscope—A tube that contains a tiny camera and light, and that is inserted in the body to allow a doctor to see inside without making a large incision.

the administration of anesthesia and the development of **blood clots**.

Results

Fasciotomy in the limbs reduces pressure, thus reducing tissue death. Endoscopic plantar fasciotomy has a success rate of 90–95%.

Fasting

Definition

Fasting is voluntarily not eating food for varying lengths of time. Fasting is used as a medical therapy for many conditions. It is also a spiritual practice in many religions.

Purpose

Fasting can be used for nearly every chronic condition, including **allergies**, **anxiety**, arthritis, **asthma**, depression, diabetes, headaches, **heart disease**, high **cholesterol**, low blood sugar, digestive disorders, mental illness, and **obesity**. Fasting is an effective and safe weight-loss method. It is frequently prescribed as a **detoxification** treatment for those with conditions that may be influenced by environmental factors, such as cancer and **multiple chemical sensitivity**. Fasting has been used successfully to help treat people who have been exposed to high levels of toxic materials due to accident or occupation. Fasting is thought to be beneficial as a preventative measure to increase overall health, vitality, and resistance to disease. Fasting is also used as a method of mental and spiritual rejuvenation.

Description

Origins

Used for thousands of years, fasting is one of the oldest therapies in medicine. Many of the great doctors of ancient times and many of the oldest healing systems have recommended it as an integral method of healing and prevention. Hippocrates, the father of Western medicine, believed fasting enabled the body to heal itself. Paracelsus, another great healer in the Western tradition, wrote over 500 years ago that "fasting is the greatest remedy, the physician within." **Ayurvedic medicine**, the world's oldest healing system, has long advocated fasting as a major treatment.

Fasting has also been used in nearly every religion in the world, including Christianity, Judaism, Buddhism, and Islam. Many of history's great spiritual leaders fasted for mental and spiritual clarity, including Jesus, Buddha, and Mohammed. In one of the famous political acts of the last century, the Indian leader Mahatma Gandhi fasted for 21 days to promote peace.

Fasting has been used in Europe as a medical treatment for years. Many spas and treatment centers, particularly those in Germany, Sweden, and Russia, use medically supervised fasting. Fasting has gained popularity in American alternative medicine over the past several decades, and many doctors feel it is beneficial. Fasting is a central therapy in detoxification, a healing method founded on the principle that the build-up of toxic substances in the body is responsible for many illnesses and conditions.

The principle of fasting is simple. When the intake of food is temporarily stopped, many systems of the body are given a break from the hard work of digestion. The extra energy gives the body the chance to heal and restore itself, and burning stored calories gets rid of toxic substances stored in the body.

The digestive tract is the part of the body most exposed to environmental threats, including bacteria, viruses, parasites, and toxins. It requires the most immune system support. When food is broken down in the intestines, it travels through the blood to the liver, the largest organ of the body's natural detoxification system. The liver breaks down and removes the toxic by-products produced by digestion, including natural ones and the chemicals now present in the food supply. During fasting, the liver and immune system are essentially freed to detoxify and heal other parts of the body.

Many healers claim that fasting is a particularly useful therapy for Americans and for the modern

WWW.BOOKBAZ.IR

lifestyle, subjected to heavy **diets**, overeating, and constant exposure to food additives and chemicals. Some alternative practitioners have gone so far as to estimate that the average American is carrying 5–10 pounds of toxic substances in their bodies, for which fasting is the quickest and most effective means of removal.

Physiology of fasting

Through evolution, the body became very efficient at storing energy and handling situations when no food was available. For many centuries, fasting was probably a normal occurrence for most people, and the body adapted to it. It is estimated that even very thin people can survive for 40 days or more without food. The body has a special mechanism that is initiated when no food is eaten. Fasting is not **starvation**, but rather the body's burning of stored energy. Starvation occurs when the body no longer has any stored energy and begins using essential tissues such as organs for an energy source. Therapeutic fasts are stopped long before this happens.

Many physiological changes occur in the body during fasting. During the first day or so, the body uses its glycogen reserves, the sugars that are the basic energy supply. After these are depleted, the body begins using fat. However, the brain, which has high fuel requirements, still needs glucose (sugars converted from glycogen). To obtain glucose for the brain, the body begins to break down muscle tissue during the second day of the fast. Thus, during fasting some muscle loss will occur. To fuel the brain, the body would need to burn over a pound of muscle a day, but the body has developed another way to create energy that saves important muscle mass. This protein-sparing process is called ketosis, which occurs during the third day of a fast for men and the second day for women. In this highly efficient state, the liver begins converting stored fat and other nonessential tissues into ketones, which can be used by the brain, muscles, and heart as energy. It is at this point in the fast that sensations of hunger generally go away, and many people experience normal or even increased energy levels. Hormone levels and certain functions become more stable in this state as well. The goal of most fasts is to allow the body to reach the ketosis state in order to burn excess fat and unneeded or damaged tissue. Thus, fasts longer than three days are generally recommended as therapy.

Weight loss occurs most rapidly during the first few days of a fast, up to 2 pounds per day. In following days, the figure drops to around 0.5 pound per day. An average weight loss of a pound a day for an entire fast can be expected.

Performing a fast

Fasts can be performed for varying lengths of time, depending on the person and his or her health requirements. For chronic conditions, therapists recommend from two to four weeks to get the most benefits. Seven-day fasts are also commonly performed. A popular fasting program for prevention and general health is a three-day fast taken four times per year, at the change of each season. These can be easily performed over long weekends. Preventative fasts of one day per week are used by many people as well.

Juice fasts are also used by many people, although these are not technically fasts. Juice fasts are less intensive than water fasts because the body does not reach the ketosis stage. The advantage of juice fasts is that fruit and vegetable drinks can supply extra energy and nutrients. People can fit a few days of juice fasting into their normal schedules without significant drops in energy. Juice fasts are also said to have cleansing and detoxifying effects. The disadvantage of juice fasts is that the body never gets to the ketosis stage, so these fasters are thought to lack the deep detoxification and healing effects of the water fast.

Medical supervision is recommended for any fast over three days. Most alternative medicine practitioners, such as homeopaths, naturopathic doctors, and ayurvedic doctors, can supervise and monitor patients during fasts. Those performing extended fasts and those with health conditions may require blood, urine, and other tests during fasting. There are many alternative health clinics that perform medically supervised fasts as well. Some conventional medical doctors may also supervise patients during fasts. Costs and insurance coverage vary, depending on the doctor, clinic, and requirements of the patient.

Preparations

Fasts must be entered and exited with care. To enter a fast, the diet should be gradually lightened over a few days. First, heavy foods such as meats and dairy products should be eliminated for a day or two. Grains, nuts, and beans should then be reduced for several days. The day before a fast, only easily digested foods like fruits, light salads, and soups should be eaten. During the fast, only pure water and occasional herbal teas should be drunk.

Fasts should be ended as gradually as they are entered, going from lighter to heavier foods progressively. The diet after a fast should emphasize fresh,

KEY TERMS

Ayurvedic medicine—A traditional healing system developed in India.

Toxin—A substance that has poisonous effects on the body.

wholesome foods. Fasters should particularly take care not to overeat when they complete a fast.

Risks

Fasting is not appropriate for everyone and, in some cases, could be harmful. Any person undertaking a first fast longer than three days should seek medical supervision. Those with health conditions should always have medical support during fasting. Plenty of water should be taken by fasters since **dehydration** can occur. Saunas and sweating therapies are sometimes recommended to assist detoxification, but should be used sparingly. Those fasting should significantly slow down their lifestyles. Taking time off of work is helpful, or at least reducing the work load. Fasters should also get plenty of rest. **Exercise** should be kept light, such as walking and gentle stretching.

Those fasting may experience side effects of **fatigue**, malaise, aches and pains, emotional duress, **acne**, headaches, allergies, swelling, **vomiting**, **bad breath**, and symptoms of colds and flu. These reactions are sometimes called *healing crises*, which are caused by temporarily increased levels of toxins in the body due to elimination and cleansing. Lower energy levels should be expected during a fast.

Results

The **physiology** of fasting has been widely studied and documented by medical science. Beneficial effects such as lowered cholesterol and improved general functioning have been shown. Fasting as a treatment for illness and disease has been studied less, although some studies around the world have shown beneficial results. A 1984 study showed that workers in Taiwan who had severe chemical **poisoning** had dramatic improvement after a 10-day fast. In Russia and Japan, studies have demonstrated fasting to be an effective treatment for mental illness. Fasting has been featured on the cover of medical journals, although mainstream medicine has generally ignored fasting and detoxification treatments as valid medical procedures.

The majority of research that exists on fasting is testimonial, consisting of individual personal accounts of healing without statistics or controlled scientific experiments. In the alternative medical community, fasting is an essential and widely accepted treatment for many illnesses and chronic conditions.

Fatigue

Definition

Fatigue is physical and/or mental exhaustion that can be triggered by **stress**, medication, overwork, or mental and physical illness or disease.

Description
